Kupffer cells exhibit an intense phagocytic activity in liver parenchyma, composing an antigen filter for substances spread by portal vein from the digestive tract. The phagocytic activity is sustained by inflammatory cytokines synthesis, such as: IL-1, IL-6, IL-12, TNF, GM-CSF, CXCL9, CXCL10, MIP-1 (macrophage inflammatory protein 1 alpha), and RANTES (regulated on activation, normal T-cell expressed and secreted) (20, 21, 22). Moreover, activated Kupffer cells express on their surface a series of molecules that provide them similar features with APC, as CD80 and CD40, in viral liver pathology (23).

Nowadays, the idea of cellular heterogeneity within Kupfferian cell population is increasingly supported not only by classic relation between dimension and location in liver sinusoids, as larger and more actively phagocytic periportal Kupffer cells as compared to centrilobular ones, the latter being smaller and especially involved in cytokines synthesis (19, 22, 24). A recent experimental study is registered in this direction, its results identifying at least two Kupfferian subpopulations, as following: CD68 (+) showing an intense phagocytic activity and CD11b (+) exhibiting the capacity of production of immunostimulatory cytokines (such as TNF and IL-12) (22). Supplementary, the hypothesis that CD68

(+) Kupffer cells might basically constitute the resident (fixed) liver Kupfferian cells population, while CD11b (+) cellular subtype might represent a migrated population of macrophage-type cells of spleen and bone marrow origin, mainly in pathologic conditions, such as inflammatory conditions (7, 25) is currently accepted.

Unfortunately, the data regarding these cells roles in viral chronic hepatitis, both with HVB and with HVC are far from being elucidated until present (12, 26).

Within this "collective effort" expressed by a multitude of studies spread by literature concerning complete phenotypic characterization of Kupffer cells, mainly in viral chronic liver pathology, our study focused on CD68 immunostaining of the existent cellular population of liver sinusoids, in 71 cases of chronic viral hepatitis, is currently framed.

Our results based on immuno-histochemical staining and Kupffer cells quantification in chronic hepatitis B and C, respectively, according to the degree of necroinflammatory activity, revealed the statistically significant increase of Kupffer cells number ($p < 0.001$) starting from the mild to moderate, and severe necroinflammatory activity, respectively. It's extremely interesting that the statistical analysis did not reveal significant differences between the numbers of Kupffer cells corresponding to each specific type of necroinflammatory activity (mild, moderate, and severe) analysis, when comparing viral hepatitis B with viral hepatitis C. Considering the pathogenic mechanism, this result may indicate the fact that the different evolution of the two types of hepatitis is not correlated to Kupffer cell number but to their specific behavior of Kupffer cells corresponding to the pathogenic agent.

Our own observations, based on Kupffer cells numerical value and their afferent score, are in agreement to literature data. Qualitative or quantitative researches aimed to highlight the sinusoidal reaction in chronic viral hepatitis, reflected in Kupffer cells number, have pointed out their progressive numerical amplification starting even from mild necroinflammatory activity types (27, 28).

The specific correlation between Kupffer cells and lymphocytes in sinusoids and the direct correlation between their number and the hepatocyte necrosis lesions intensity have been some of the first morphological aspects observed in light microscopy. Thus, McGuiness and al., by comparing CD68 (+) Kupffer cells number in 10 cases of chronic hepatitis, observed an increase of their number associated to a dispersion into the liver lobule, in comparison to control cases (24).

The Kupfferian hyperplasia is far more important as viral chronic hepatitis has been appreciated with a higher aggressiveness. Quantitative analysis of the area occupied in liver parenchyma by immunolabeled Kupffer cells confirms the results of the study. The authors observed a progressive increase in the percentage occupied by Kupffer cells in total area of liver surface correlated to disease severity, ranging from 2.51 ± 0.88 in moderate activity and 4.71 ± 2.23 in severe activity types of chronic hepatitis (29).

The involvement of Kupffer cells in Ito cells activation and in fibrillogenic activity in liver parenchyma have been unanimously recognized (8, 30, 31). However, the molecular aspects of interactions between activated liver macrophages and myofibroblasts are still incompletely known, repre-

senting a point of interest directed toward identification of new possible therapeutic targets in liver fibrosis (32).

Kupffer cells and fibrosis – Ishak score

Recent studies have shown that HVB chronic liver infection even in cases exhibiting a mild necroinflammatory activity is associated to sinusoidal and portal collagen synthesis development. This phenomenon is attributed to Kupffer cells reactivity even in mild aggressiveness hepatitis types to produce a panel of pro-fibrillogenic cytokines, such as TGF-β1 (33).

It is unanimously accepted that patients with HVC have more severe fibrosis lesions compared to HVB chronic hepatitis patients (34). Our results confirmed this assertion.

The evaluation of the fibrosis severity correlated to the necroinflammatory activity has revealed more important lesions in chronic hepatitis C. Compared to chronic hepatitis B, more cases with fibrosis of score 2 and 3 showed mild necroinflammatory activity. Compared to chronic hepatitis B, no case showed score 1 fibrosis and score 4 fibrosis was detected in moderate necroinflammatory activity. All cases showing severe necroinflammatory activity had fibrosis score 4, when compared to chronic hepatitis B.

We have registered statistically significant differences between Kupffer cells number associated to cases with fibrosis score 1 and 2, and score 3 and 4, respectively, in each hepatitis type ($p < 0.001$). We have also noted that the score value correlated to Kupffer cells expression increased from 1 to 3 in chronic hepatitis B and from 1 to 2 in chronic hepatitis C, corresponding to mild and severe fibrosis, respectively. However, despite the above mentioned fibrosis score in the same intensity of the necroinflammatory activity, statistical analysis revealed the lack of statistically significant differences between chronic hepatitis B and C, correlated to Kupffer cells number in fibrosis score 1 and 2 fibrosis score and 3 and 4, respectively.

This negative result supports the idea of fibrosis development as an event not necessarily related to Kupffer cells. The dramatic changes of the last 10-15 years concerning liver fibrosis have been closely correlated to the deciphering of the extracellular matrix dynamic and ultrastructure, to the elucidation of the liver myofibroblasts biology and, not the last, the integration of all these new elements in the complex process nowadays known as "connective repair" (the integrated wound healing response) (35, 36).

Kupffer cells, necroinflammatory activity, and fibrosis – Metavir score

Although Metavir score assures a specific and reproducible evaluation in C viral hepatitis (37), being largely used in histopathologic diagnosis formulation, the mainstream publication review revealed the complete lack of the researches oriented towards the relationship between Kupffer cells and lesions severity, corresponding to Metavir score categories in this type of hepatitis. To our knowledge, there is only a single study that quantifies Kupffer cells and is analyzing their dynamic related to the F (fibrosis) parameter of Metavir score, in the pathologic context of chronic hepatitis induced by chronic alcohol consumption and of fibrosis that develops in the evolution of this disease (38). The mentioned study indicates the lack of a direct correlation between CD68 expression, as a marker

of Kupffer cells, and the degree of severity of the disease, progressively from stage I to III (38).

Within this context we consider that our data have a degree of novelty supported by the differences obtained by comparison of the results obtained by the use of the two scores, Ishak and Metavir. In our opinion, the 3 classes of severity A1F1/A1F2, A2F1/A2F2, and A3F3 of Metavir score more likely reflect the lesions evolution, including the correlation between the necroinflammatory activity and fibrosis than the severity classes separately defined by necroinflammatory activity and fibrosis, respectively, in Ishak score. The most convincing argumentation is provided by the 4 cases that, according to Metavir score, have been framed into a higher category of severity, by A3F3 score. The statistically significant differences between Kupffer cells number (median and SD) in all 3 classes of Metavir severity indicate the involvement of Kupffer cells in enhancement of both inflammation and fibrosis, during the lesions severity evolution in C hepatitis.

In our current activity, the additional use of Ishak score in chronic hepatitis C is justified by the fact that the large numerical value scale correspondent to necroinflammatory and fibrosis activities evaluation offers more precise criteria to evaluate the status of liver parenchyma involvement at the diagnosis moment and METAVIR score, simultaneously applied, allows an evaluation of the general histologic activity, including the interface hepatitis and of associated components of lobular necrosis.

As a consequence of the study oriented towards the quantitative profile of Kupffer cells, we may appreciate that Metavir score offers, by numerical values, an image of the inflammatory process and of fibrillogenesis that includes, as a pathogenic substrate, including Kupffer cells involvement.

CONCLUSIONS

The sinusoidal reaction in chronic liver diseases of viral etiology expressed by CD68 (+) cells hyperplasia progressively increases along with the intensity of necroinflammatory activity and with the amplitude of fibrosis lesions. The classic microscopically findings, the quantitative evaluation, and the statistical analysis indicate the involvement of Kupffer cells, directly correlated to the severity degree of the disease, without differences between B and C chronic hepatitis. Consequently, we may appreciate that the chronic hepatitis C specific lesions progression, different from that of chronic hepatitis B, is influenced by a different behavior of Kupffer cells, and not by their effective number.

SIGNET-RING CELL MELANOMA OF THE GASTROESOPHAGEAL JUNCTION

Malignant melanomas are well-known for demonstrating a wide range of microscopic appearances and, therefore, simulate other tumor types. Consequently, melanomas with unusual phenotypes may present a diagnostic challenge to the surgical pathologist. Signet-ring cell melanoma of the gastroesophageal junction is the first case of probable primary signet-ring cell melanoma at this site and the second case reported in the gastrointestinal tract. Signet-ring cell melanoma is defined as a melanoma with more than 50% of tumor cells having signet-ring–shaped nuclei because of compression by intracytoplasmic globules. Signet-ring cell morphology is extremely rare in melanomas (0.5%) and is one of 5 unusual variants described in a review of diversity in melanomas by Nakhleh et al. Signet-ring cell melanoma was first described in 1988 by Sheibani and Battifora. In 2 reported cases, transmission electron microscopy was used to identify melanosomes, premelanosomes, and discrete aggregates of intermediate filaments distending the cytoplasm. The signet-ring cells in each of these cases strongly expressed S100 protein, HMB-45, and vimentin, confirming the diagnosis. Since the entity was first described, only 19 additional cases have been reported in the literature. Approximately one-half of those cases were metastases or recurrences, with only 8 cases reported as primary lesions. The diagnosis can be confirmed by the presence of immunoreactivity for melanocytic markers, the absence of mucin and immunohistochemical staining for pancytokeratin, and if necessary, examination for ultrastructural features including melanosomes, in signet-ring cell morphology tumors. (Melissa A, Grilliot, R. Goldblum, Xiuli Liu. Signet-Ring Cell Melanoma of the Gastroesophageal Junction. *Arch Pathol Lab Med*. 2012;136:324–328).

THE INCIDENCE OF ESSENTIAL HYPERTENSION IN ELDERLY PATIENTS WITH METABOLIC SYNDROME

THE INCIDENCE OF ESSENTIAL HYPERTENSION (EHT) IN ELDERLY PATIENTS WITH METABOLIC SYNDROME ASSISTED AT THE REHABILITATION HOSPITAL IASI, DURING OCTOBER 2010-JULY 2012 (Abstract): The arterial hypertension of the elderly represents an important public health issue, with an ever increasing tendency, due to the population ageing process. **Aim:** The aim of this research is to contribute new data related to the incidence of essential hypertension in elderly patients with metabolic syndrome. **Material and methods:** The current study was conducted on a number of 1,832 patients hospitalized in the Cardiovascular Rehabilitation Clinic of Rehabilitation Hospital Iasi, in the period October 2010-July 2012. Of these patients we selected the ones who were 65 years of age or more and who fulfilled at least three of the five criteria that define the metabolic syndrome, using the criteria recommended by AHA/NHLBI. **Results:** The data obtained revealed an increased incidence of the cardiometabolic syndrome in patients over 65 years of age, in a percentage of 73%. The gender repartition revealed a higher frequency in the case of female patients (66%). Of the metabolic syndrome criteria, the highest incidence was registered for the essential hypertension. Most of the hypertensive patients were diagnosed with essential hypertension grade 3 (55%), while the rest had grade 2 (29%) and grade 1 respectively (16%). **Conclusion:** EHT has a significant occurrence in elderly patients. It seems that hypertension of the elderly has a higher occurrence in the case of female patients, due to the lack of hormonal protection. The association with the other risk factors related to the metabolic syndrome makes the elderly more prone to the occurrence and development of cardiovascular diseases. **Keywords**: ESSENTIAL HYPERTENSION, ELDERLY PEOPLE, METABOLIC SYNDROME.

The metabolic syndrome is defined as a group of risk factors leading to cardiovascular disease, whose pathophysiological foundation is related to insulin resistance. Clinical studies have shown that not all patients presenting metabolic syndrome are really insulin resistant, and consequently other cardiovascular risk factors are considered, including essential hypertension, type 2 diabetes mellitus, hyperlipidemia, obesity and others (1, 2). Over the last two decades, the International Health Organization and the National Institutes of Health, together with the American Heart Association have provided several precise definitions of the metabolic syndrome (3, 4).

Arterial hypertension represents the main risk factor in elderly patients, increasing the incidence of coronary and cerebral vascular accidents. Epidemiological studies have shown that most elderly male and female patients have a systolic pressure above 160 mm Hg, while the diastolic pressure is less than 100 mm Hg. As far as patient gender is concerned, it seems that hypertension in elderly patients has a higher occurrence in women (5). Systolic arterial hypertension commonly occurs in elderly patients, but essential forms (systolic-diastolic) can also be detected.

MATERIAL AND METHODS

We investigated the medical records of 1,832 patients hospitalized in the Clinic of Cardiovascular Rehabilitation Clinic of Rehabilitation Hospital Iasi in the period October 2010 – July 2012. We selected the patients over 65 years of age who fulfilled at least three of the five criteria defining the metabolic syndrome. We used the criteria recommended by AHA/NHLBI (American Heart Association). Any three criteria of the five listed establish the metabolic syndrome diagnosis (tab. I).

Of the total of 1,832 patients we selected a number of 239 patients over 65 years of age. The patients were divided according to age groups (patients over 65 years of age and patients under 65 years of age), gender and the presence or absence of the metabolic syndrome as well as taking into account the essential hypertension grade and the number of clinical criteria used in establishing the metabolic syndrome diagnosis (3, 4 or 5 criteria). The frequency of each criterion was then recorded in each subgroup presenting 3, 4 and respectively 5 diagnosis criteria.

TABLE I

Diagnostic criteria for metabolic syndrome (according to AHA / NHLBI)

Clinical criteria (at least 3)	Normal values of the parameters
waist circumference (WC)	≥102 cm in men ≥88 cm in women
serum triglycerides level (TG)	≥150 mg/dl or with treatment for high levels of TG
high-density lipoprotein cholesterol level (HDL)	<40 mg/dl in men <50 mg/dl in women or with treatment for low levels of HDL↓
blood pressure (BP)	≥130 mmHg BP sistolic or ≥85 mmHg BP diastolic with treatment for hypertension
serum glucose level (Glu)	≥100 mg/dl or with treatment for diabetes

RESULTS

From the 1,832 patients hospitalized during that period, only 239 are over 65 years of age. (fig.1). The statistical analysis of the data shows that the number of patients over 65 years of age is statistically significant in comparison with the rest of the patients studied ($p<0.01$).

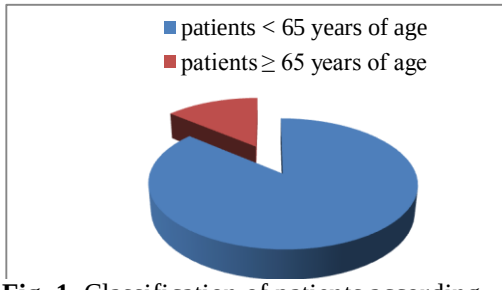

Fig. 1. Classification of patients according to age groups

From the 239 patients who were 65 or older, 174 (73%) were diagnosed with

metabolic syndrome according to the above mentioned criteria (fig. 2). The statistic analysis of the data revealed a significant difference, the value of the p coefficient being under 0.01.

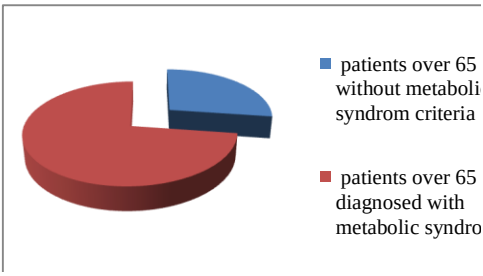

Fig. 2. Classification of patients according to the presence/absence of the metabolic syndrome

From the total number of patients diagnosed with metabolic syndrome, there are 115 female patients and only 59 male patients (fig. 3). The number of female patients is significantly higher than the number of male patients ($p<0.01$).

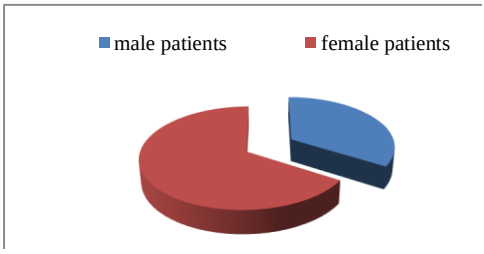

Fig. 3. Classification of patients according to gender

From the 174 patients diagnosed with metabolic syndrome, 104 met just 3 criteria, 50 met 4 criteria while just 20 patients met all 5 criteria of the metabolic syndrome. The statistically significant difference is to be found between the patients meeting 4 or 5 criteria of the metabolic syndrome and the total number of patients included in the study.

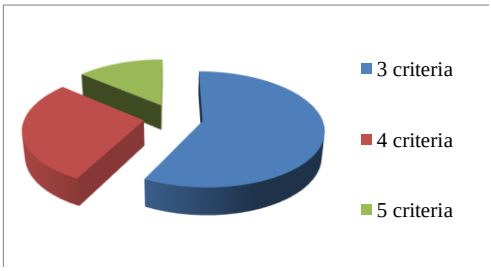

Fig. 4. Classification of patients according to metabolic syndrome criteria

Most of these patients were diagnosed with essential hypertension grade 3 (55%), while the others presented essential hypertension grade 2 (29%) and grade 1 (16%) (fig. 5).

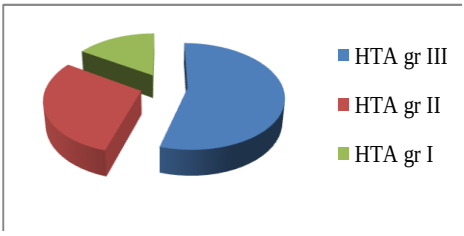

Fig. 5. Classification of patients according to hypertension grade

DISCUSSION

From the total number of 234 patients who fulfilled the age criteria, 73% were diagnosed with metabolic syndrome. The metabolic syndrome incidence was higher in the case of female patients (66%) than in the case of male patients (34%), according to data provided by the literature (6). 59% of the patients had 3 diagnosis criteria, 29% met 4 criteria and only 14% met all 5 criteria. The highest incidence of all criteria used in the metabolic syndrome diagnosis is represented by the essential hyperten-

sion. Most hypertensive patients were diagnosed with essential hypertension grade 3 (55%). In the case of these patients, arterial hypertension may be considered a marker of endothelial dysfunction that leads to the cardiometabolic syndrome. At the same time, endothelial dysfunction is the starting point for the occurrence and development of the atherosclerotic process.

The Framingham study showed that arterial hypertension continues to be a major cardiovascular risk factor that favors atherogenesis. Normal correlations between arterial preessure and age: after the age of 60, systolic blood pressure increases while the diastolic blood pressure decreases (the Framingham study), the changes in arterial pressure having the same meaning for hypertensive patients and patients with normal arterial tension. The isolated arterial hypertension: systolic blood pressure > 140 mm Hg with diastolic blood pressure < 90 mm Hg (implies a pulse pressure above 60 mm Hg). As well as this, the present study provides important prevalent data. Thus, arterial hypertension affects 60-80% of the population over 65 years of age, while isolated systolic hypertension represents 65-75% of the total cases of arterial hypertension in elderly people.

Other epidemiological studies have shown that arterial hypertension has a higher occurrence in overweight people, especially when obesity affects the superior part of the upper body. Obesity represents a risk factor for hypertension as well as for diabetes, cardiovascular disease, osteoarthritis and some forms of cancer (8, 12). Arterial hypertension occurs in 60-70% of diabetics and is at least twice as frequent in this category of patients as compared with non-diabetics. Arterial hypertension increases the cardiovascular risk by micro- and macro- diabetic angiopathy (cardiovascular modifications at the eye level). The association between arterial hypertension and high cholesterol levels increases the cardiovascular risk in diabetics (9).

The prognosis and evolution of arterial hypertension depend on the recorded tension values and the early diagnosis. Untreated arterial hypertension is known as a risk factor that favors the installation and unfavorable evolution of atherosclerosis, leading to cardiac complications (ischemic cardiopathy), stroke, stenosis of the carotid arteries or of the inferior limbs vessels (arthritis). It was noted that 50% of hypertensive patients present ischemic cardiopathy, while the patients with a heart attack have a history of arterial hypertension (10, 11).

The coexistence of other risk factors such as: smoking, obesity, alcohol consumption, sedentary life-style, excess of salt, hyperuricemia (abnormally high level of uric acid in the blood), high blood sugar level and high consumption of animal fat, accelerates the atherosclerosis evolution and leads to arterial hypertension.

The results from the different elderly study populations link the presence of the metabolic syndrome with the development of cardiovascular diseases and functional disability, and further underscore the importance of recognizing and treating its individual components, particularly high blood pressure (12, 13, 14).

CONCLUSIONS

Arterial hypertension in elderly people represents an important public health issue, with an ever increasing frequency, due to the population ageing process. Due to the associated cardiovascular conditions, risk factors and damages to the target organs

that are more serious than in the case of young adult patients, arterial hypertension in elderly patients remains an incompletely defined condition, open to speculations related to its pathogenic mechanisms as well as its treatment possibilities.

THE ASSESSMENT OF TREATMENT EFFICACY IN AGE RELATED MACULAR DEGENERATION BY EVALUATING THE OXIDATIVE STRESS MARKERS AND OCT MEASUREMENTS (Abstract): Age related macular degeneration (AMD) is the most frequent cause of blindness in the elderly. **Aim**: to establish the role of oxidative stress in retinal structural lesions in AMD and to monitor the evolution of oxidative stress markers and OCT measurements before and after treatment. **Material and methods**: This is a case-control study that included 19 patients diagnosed with AMD and 40 matched healthy controls. According to the AREDS classification, patients were divided into mild, moderate and severe AMD and received treatment with antioxidants, neurotrophic drugs, intravitreal corticosteroids and/or anti-VEGF. We followed the patients by assessment of visual acuity, optical coherence tomography (OCT) and oxidative stress markers, such as superoxide-dismutase (SOD), thiobarbituric acid reactive substances (TBARS), and C-reactive protein (CRP) from blood samples before and after treatment. **Results**: The OCT showed that the macular edema in patients with severe disease was significantly reduced after treatment, while the cases with normal retinal thickness increased significantly ($p=0.005$). Comparing the mean values of SOD, TBARS and CRP in the two groups, we found that they were significantly higher in the study group compared to controls ($p<0.01$), being higher in patients with severe disease. These values decreased post treatment, but they were still higher than in controls. **Conclusions**: The present research supports the role of oxidative stress and inflammation in AMD and highlights the role of therapy directed against these risk factors. By monitoring the oxidative stress markers in the evolution of the disease, we showed that high values persist after treatment, thus supporting the idea that treatment should be followed for a long time. **Keywords**: AGE RELATED MACULAR DEGENERATION, OXIDATIVE STRESS MARKERS, ANTI-VEGF.

Age related macular degeneration (AMD) is the leading cause of blindness in developed countries. This is a set of degenerative and inflammatory lesions in the macular region, which occurs in previously normal eye and cause a deterioration of central vision and macular function (1). The increasing incidence, the lack of methods of preventing AMD and the negative socio-economic consequences make it a priority among ophthalmic diseases. The current treatment includes systemic treat-

ment with antioxidants and local intravitreal injections with corticosteroids and /or anti-angiogenic factors, photodynamic therapy and macular surgery.

The aim of this study is to assess the role of oxidative stress in AMD lesions and to monitor the evolution of oxidative stress markers pre-and post treatment. We aimed to establish the efficacy of antioxidants, neuroprotectors, intravitreal corticosteroids and anti-VEGF, as well as to establish correlations between functional and structural changes and oxidative stress markers before and after treatment.

MATERIAL AND METHODS

This is a case-control study that included a group of 19 patients diagnosed with AMD, selected from the "N. Oblu" Hospital in Iaşi, and two control groups, one with younger controls and another with controls with similar ages as the cases. Patients with systemic and ocular diseases that could increase oxidative stress, such as diabetes, inflammatory and infectious diseases or vascular occlusions were excluded. According to the law on patients' rights, they signed an informed consent. We explained to them the visual prognosis and the treatment methods.

The follow-up period was for a median of 8 months. Depending on the severity of the diagnosis, patients were divided into 3 groups according to the classification of "Age-Related Eye Disease Study" (AREDS) of the U.S. National Eye Institute: group 1 – mild AMD, group 2 – moderate, atrophic AMD, group 3 – severe neovascular AMD. Patients received treatment with antioxidants, neuroprotectors and intravitreal injections with corticosteroids and/or Avastin. We recorded the visual acuity, anterior pole biomicroscopy, posterior pole appearance (Volk 78 D lens), Optical Coherence Tomography (OCT) and laboratory tests before and after treatment. As regards the laboratory tests, we followed the oxidative stress markers such as thiobarbituric acid reactive substances (TBARS), antioxidant enzymes – superoxide dismutase (SOD), and markers of inflammation – C-reactive protein (CRP). In the study group there were included only patients with severity level 2 and 3. The retinal thickness and retinal nerve fiber layer were measured with Spectral OCT OPTOPOL in 9 quadrants.

SOD activity was determined by xanthine oxidase method, TBARS were quantified by colorimetric method and CRP measurement was made by immune-turbidimetry with calibrator. We assessed the treatment efficacy by studying the evolution of visual acuity, OCT measurements and biomarkers' levels post treatment.

The statistical analysis (performed with the Statistical Programme 7.0) was intended to highlight significant correlations between the structural and functional changes and the results of the blood tests. We also wanted to evaluate the effects of treatment by comparing data obtained before and after treatment. The statistical comparison was made with "Difference tests" from the sub-set of descriptive statistic programs, being significant those differences which stood at a safe threshold of 95% ($p < 0.05$).

RESULTS

We investigated a group of 19 subjects, 8 males (42.11%) and 11 women (57.89%) with a mean age of 72.47 ± 7.74 years (59 to 88). The first control group (elder group) included 11 subjects (3 men and 8 women), with ages ranging between 60 and 85 years.

We used the second control group (younger group), which comprised of 40 subjects (11 men and 29 women), aged between 28 and 60 years, in order to compare the laboratory results.

The patients were treated with local injections with intravitreal Avastin and/or corticosteroids, systemic antioxidants and neuroprotectors, alone or in combination, according to individualized treatment regimens. Patients received an average of 4 injections with corticosteroids and 3 with Avastin.

We analyzed the effects of the treatment in the study group, comparing retinal thickness measurements and the blood results before and after treatment. In patients with the wet form, the mean retinal thickness was 347 273 µ, signifying the presence of macular edema. In patients with dry form, the mean retinal thickness was 257.47µ, falling within normal limits. After treatment, patients, in whom the macular edema reduced, falling within the normal values of macular thickness, were included in severity class 2. We also included in severity class 2 those patients in which the neurosensitive retinal detachment was reduced significantly (fig. 1).

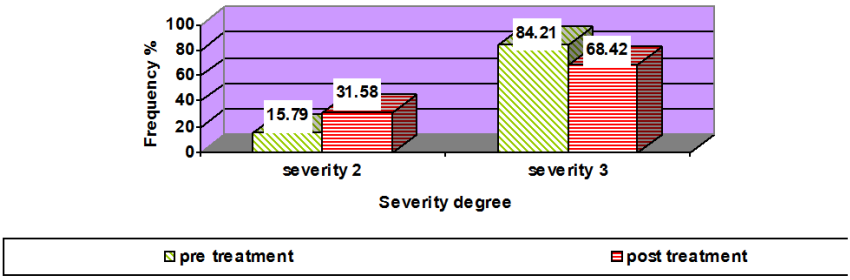

Fig. 1. The frequency of cases before and after treatment

After treatment there was a significant reduction (p = .02) of cases with a visual acuity worse than 0.30. Although not statistically significant, we note that after treatment there was an increase of cases with visual acuity between 0.30 and 0.40.

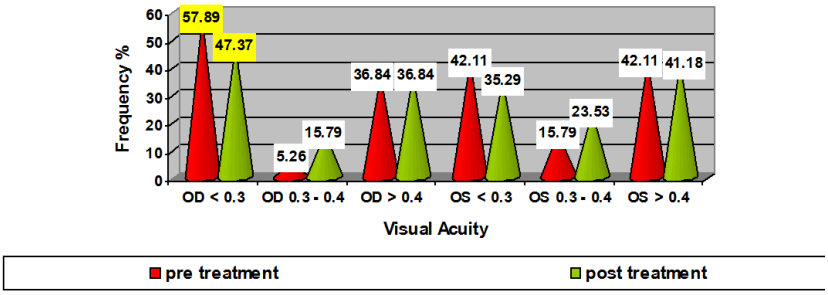

Fig. 2. The evolution of visual acuity before and after treatment

We noticed that after treatment, the incidence of macular edema decreases (fig.3). The frequency of cases with normal retinal thickness increased significantly

from 36.84% to 81.25%.

It appears that the frequency of atrophy after treatment decreased, even if we did not find it to be statistically significant. We measured the levels of oxidative stress and inflammatory markers such as SOD, TBARS and CRP in the study group pre and post treatment and in the control groups at the initial visit. The mean values of SOD, TBARS and CRP in the study group were slightly higher at the first examination compared to the second examination, made after treatment (tab. I).

The mean values of SOD, TBARS and CRP in the study group were significantly higher both before and after treatment compared to the values in the control group. Both before and after treatment, it was found that the mean values of SOD, TBARS and CRP were significantly higher in subjects with a diagnosis of severity level 3 (fig. 4, 5).

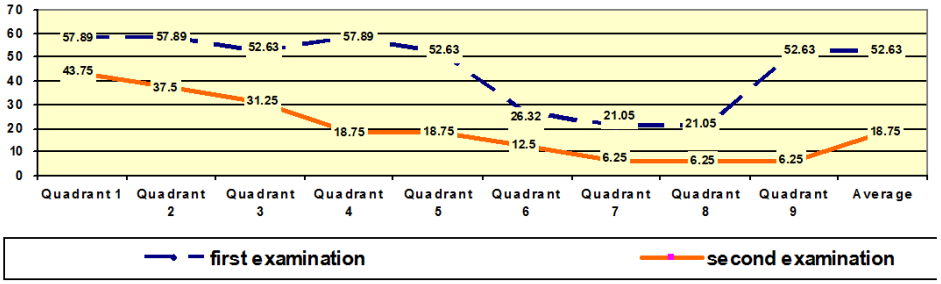

Fig. 3. The frequency of retinal edema before and after treatment

TABLE I

The mean values of the oxidative stress markers

	Number	SOD (U/ml)	TBARS (nmols/ml)	CRP (mg/dl)
Study Group before treatment	19	331.78	4.62	3.25
Study Group after treatment	19	313.15	4.31	2.87
Elderly Control Group	11	269.54	3.90	1.49
Younger Control Group	40	196.05	3.02	0.81

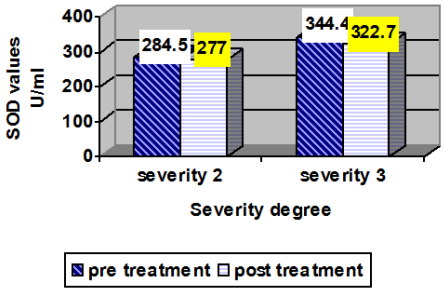

Fig. 4. The mean values of SOD pre and post treatment

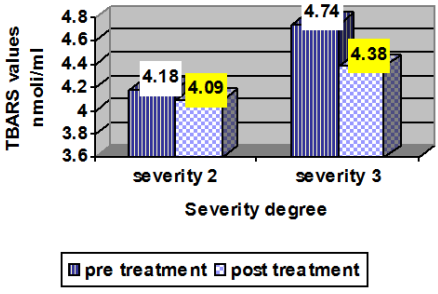

Fig. 5. The mean value of TBARS pre and post treatment

DISCUSSION

In the present study the treatment was performed with intravitreal injections with Avastin and/or corticosteroids, systemic antioxidants and neuroprotectors, alone or in combination, according to individualized treatment regimens. After treatment, the cases with severity level 3 were reduced from 84.21% to 68.42%, increasing the frequency of cases with severity level 2 from 15.79% to 31.58%. In terms of visual acuity, there was a significant reduction in the frequency of cases with a visual acuity below 0.30 from 57.89% before treatment to 47.37% after treatment and an increase in the frequency of cases with visual acuity between 0.30 and 0.40.

We noticed that the frequency of edema decreased significantly from the first examination to the second examination and the frequency of cases with normal retinal thickness significantly increased from 36.84% to 81.25%.

Treatment effects were supported by various studies. A new study showed new ways to treat atrophic and wet AMD. These included neuroprotection, prevention of oxidative stress and suppression of inflammation (2). AREDS study showed a significant benefit of the combination of vitamins and antioxidants, reducing the risk of complications in advanced AMD. The risk of progression was reduced by 25% for the entire study population and by 34% for patients with advanced AMD (3).

Some patients were treated with both Avastin and corticosteroid, and we observed a significant improvement both at the functional level (visual acuity) and at the structural level (assessed by OCT). The close link between the pathogenesis of CNV and VEGF-A expression suggests that VEGF-A inhibition may be a viable treatment in wet AMD. Trials such as VISION (4, 5), MARINA (6), ANCHOR (7), and Pronto (8) showed the benefits of treatment with anti-VEGF. An increase in visual acuity correlated with an improvement on the OCT was observed. CATT 2 study showed good results in maintaining visual acuity both with Avastin and Lucentis injected every 4 weeks (9). A recent study supports the importance of neuroprotective therapy in AMD. There are three neuroprotective-therapy strategies: ciliary neurotrophic factor, Brimonidine and fluorocinolon acetonide (10). The neuroprotective effect of corticosteroids on photoreceptors and RPE was suggested in a study by Glybina and collaborators. They showed that mice treated with fluorocinolon acetonide presented less atrophy and a smaller decline in the ERG b-wave amplitude. Sustained release decreases the retinal inflammation (11).

As regards the antioxidant enzymes and inflammatory markers, the present study showed that the average values of SOD, TBARS and CRP in the study group were significantly higher than those recorded in the control group. The mean values were significantly higher at the first examination compared to the second examination, made after treatment. After treatment, values were still above the normal range, suggesting the need for a long term treatment. The results are consistent with other studies supporting the fact that oxidative stress plays a key role in this disease (12, 13, 14).

CONCLUSIONS

The present research supports the role of oxidative stress and inflammation in AMD, and highlights the role of therapy directed against these risk factors. We found that after treatment, the frequency of

cases with macular edema decreases, while the frequency of cases with normal retinal thickness significantly increases. The mean values of SOD, TBARS and CRP in the study group were significantly higher both pre- and post-treatment, according to disease severity, compared to the values in control group. This suggests that treatment should be followed for a long time. The mean values of blood markers in the study group were slightly higher in the first examination compared with the second examination, after treatment, supporting its beneficial effect.

IMMUNE REGULATORY PLASMACYTOID DENDRITIC CELLS SELECTIVELY ACCUMULATE IN PERITHYROIDAL LYMPH NODES OF PATIENTS WITH GRAVES DISEASE: IMPLICATIONS FOR THE UNDERSTANDING OF AUTOIMMUNITY(Abstract): Endocrine orbitopathy(EO) is the most common extrathyroidal manifestation of Graves disease (GD) but the involvement of the underlying immunological dysregulations remains largely unknown. The major source for IFNα-production, plasmacytoid dendritic cells (PDC) are fundamentally involved in the integration of TH1 and TH2 immune responses but also implicated in the pathogenesis of autoimmune diseases such as lupus. **Aim**: To establish whether PDC may play a role in GD autoimmune reaction and in the pathogenesis of EO. **Material and methods**:In a series of six sequential patients with GD as well as six further patients with multinodular goiter, cervical lymph nodes (LN) were sampled and preserved in the setting of thyroid resection. In parallel, peripheral blood samples were collected. The frequency of PDC from the peripheral blood and lymph nodes were determined. Mononuclear cells (MC) were enriched from lymph nodes and peripheral blood using Fiquoll-hypaque density gradient centrifugation. Mononuclear cells were stained using BDCA-2-PE and CD123-FITC monoclonal antibodies and their frequency subsequently analyzed using fluorescence activated cell sorting (FACS). Dead cells were excluded from analysis by appropriate gating strategies and propidium iodide (PI) staining. **Results**:In all patients with GD (with or without EO), PDC frequency was significantly increased in perithyroidal LN as compared to LN of patient not suffering form autoimmune diseases, e. g. patients with multinodular goiter ($p < 0.01$). The number of PDC infiltrating lymph nodes (LN-PDC) was also higher when compared to peripheral blood PDC (pB-PDC) of patients with multinodular goiter ($p < 0.05$). Finally, LN-PDC counts in perithyroidal lymph nodes of patients with GD were substantially increased when compared to pB-PDC of the same patients ($p < 0.01$) indicating a migration and accumulation of PDC in the draining LN. **Conclusions**: We found evidence that PDC selectively accumulate in perithyoidal LN of patients with GD, but not other thyroid diseases such as multinodular goiter. Based on their central importance in the pathogenesis of autoimmune processes such as in lupus erythematoides, we suggest

that the migration and accumulation of PDC in an anatomical joining point between the thyroid gland and orbita may be of critical importance for the initiation and maintenance of a chronic autoimmune stimulation. This implies a so far unknown role for PDC in GD and as putative cellular targets for new therapeutic approaches. **Keywords**: GRAVES DISEASE, IMMUNEREGULATORY PLASMACYTOID DENDRITIC CELLS, ENDOCRINE ORBITOPATHY, SURGERY

A common part of Graves' disease (GD) clinical picture (90–95 %), the endocrine orbitopathy(EO) appears less frequently in Hashimoto's thyroiditis and rarely unrelated to other thyroid conditions (0,5-5 %). About half of the GD patients have clinically obvious ocular signs, mostly of mild to medium severity, while only 3–5 % of the cases develop a severe EO, with optical nerve compression (1). Typically the EO occurs in the first 6 months from the onset of the thyroid hyperfunction (46-60%) although in 30% of the cases the ocular signs may appear after years, frequently associated with a relapse of the hyperthyroidism. This correlation between the onset of hyperfunction and EO suggests a common pathogenetical mechanism. The pathogenesis of EO comprises an increase of retroocular fibroadipose tissue and swelling of extraocular muscles and orbital connective tissues, due to an infiltration with lymphocytes (T cells), mastocytes and macrophages. A cytokine-related activation of the local connective tissue cells generates an increased production of glycosaminoglycans responsible for the appearance of edema as well as an increased adipogenesis, both resulting in an enlargement of the orbital tissue volume. An overexpression of TSH-R during the differentiation of preadipocytes was noted, underlying the role of TSH-R as an autoantigen in the orbita, which was confirmed by a number of studies on animal models (2).

In contrast to other regions of the body, the orbital fibroblasts express CD40. Normally present on the surface of B-cells, macrophages and dendritic cells, CD40 binds to the CD40-ligands (CD154) activated T-cells and subsequently stimulates the production of cytokines by macrophages. CD40-ligation determines orbital fibroblasts to express IL6 and IL8 (with subsequently enhanced chemotaxis and migration of immune competent cells in the orbita) as well as to activate inflammatory cyclooxygenases (by production of prostaglandine E) and raise the production of hyaluronic acid. Considering that cervico-regional lymph nodes are almost constantly enlarged in cases of Graves' disease, the aim of this pilot study was to investigate the role of the plasmacytoid dendritic cells (PDC) from the perithyroidal lymph nodes, as antigen presenting cells and major IFNα source, in the pathogenesis of autoimmune mechanism of the disease and particularly of EO.

MATERIAL AND METHODS

A series of 10 consecutive patients with GD as well as a series of 10 patients with multinodulareuthyroid goiter were enrolled in this study. In all cases, besides thyroidectomy, perithyroidal cervical lymph nodes (LN) were sampled. In the mean time, peripheral heparine-blood samples (20 ml) were collected. Fiquoll-hypaque density gradient centrifugation was used in order to isolate multinuclear cells (MNC) from LN and blood. To obtain LN tissue, the LNs were previously pressed on ice through a mesh, always on the day of the operation,

to avoid the loss of cells.

By fluorence-activated cell sorter (FACS) following a staining of the PBMC with two monoclonal antibodies (BDCA-2-PE und CD123-FITC), PDC were identified as a clearly defined and highly quantifiable population. The percentage of double positive cells was referred to percentage of MNC. Dead cells were excluded by appropriate gating techniques and propidium iodide (PI) staining. When sufficient material was available, a separation of PDC from MNC was performed by magnetic automated cell sorting (MACS), in order to provide RNA for further genetic testing (cDNA arrays). However, the purity after BDCA-4 MACS was approximately 30 % only. The staining of the MNC followed by monoclonal antibodies as previously mentioned. For immunostaining of TSH receptor in the LN of GD patient samples were fixed in 10% neutral buffered formalin for 24 hours then embedded in paraffin as a routine procedure. Sections were immunostained with a 1:250 diluted polyclonal anti-TSH Ab (Dako, Glostrup, Denmark). Detections were carried out using biotin-streptavidin and counterstained with Hämalaun for 10 sec to visualize nuclei.

RESULTS

Immunohistochemistry showed a powerful expression of TSH-receptors in the perithyroidal LN of the patients with GD and EO (fig. 1).

In all GD patients, irrespective of EO, the frequency of PDC was significantly higher in perithyroidal LN compared to normal cervical LN, sampled from patients with euthyroid goiter ($p < 0.01$).

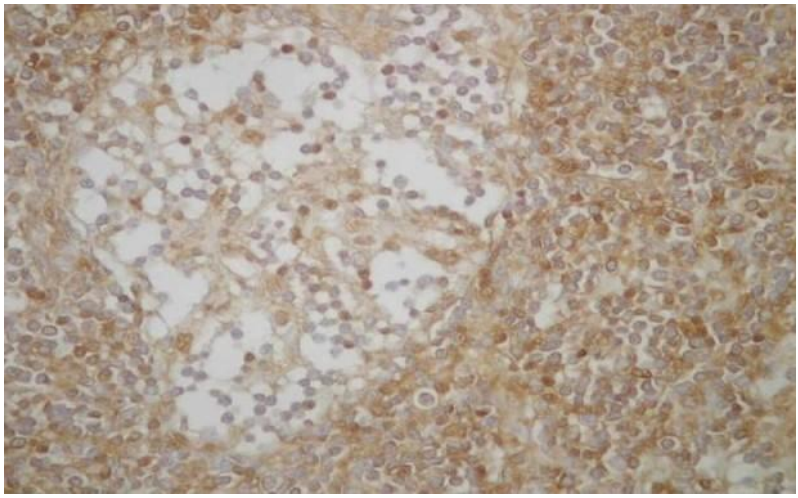

Fig. 1. Positive anti TSH-Receptor immunostain in perithyroidallymphnodes of patients with GD and EO

In a series of healthy patients and normal LN, the initial frequency of PDC was mean 0.4 % of MNC in blood compared to 0.2–0.3 % of MNC in LN. Higher frequencies of lymph nodes-PDC (LN-PDC) were always recorded in GD patients compared to peripheral blood (pB-PDC) ($p < 0.05$). And, above all, LN-PDC was significantly higher than pB-PDC in GD patients ($p < 0.01$)(fig. 2, 3).

DISCUSSION

As previously noted by Kriss et al. (3), in GD, hyperthyroidism and ocular disease share a common pathogenetical mechanism. They further formulated the hypothesis that regional LN may be the site of antibody presentation and processing. This was supported by the particular observation

of common lymph drainage pathways of thyroid and orbita. In 1970, Kriss and coworkers published the results of a thyroid 99Tcm colloid scintigraphy study, showing that in patients with GD and EO, compared to patients with other forms of hyperthyroidism or nodular thyroid diseases, a rapid and massive fixation of radionuclide occurs in cervical nodes bilaterally. They also proved the communication between the orbita and cervical LN through the inferior orbital fissure, allowing a deposition of antigen structures and the autoimmune reaction in both cervical LN and orbita. A clear correlation was established between the severity and activity of EO and the involvement of cervical LN, which Kriss thought at that time to be favourised by thyroglobuline(TG)(3). The enlargement of cervical LN by patients with GD has been previously noted by surgeons.

A single center two-armed prospective randomized study was published in 1998, comparing the results of subtotal thyroidectomy with or without cervical lymphadenectomy in GD and EO. In a follow-up period of three years, the authors monitored the titer of antibodies, thyroid function and development of EO by orbital MRT. A significant reduction of EO was noted for patients with thyroid resection and lymphadenectomy compared to patients with thyroidectomy only. Objectively assessing the severity of EO the volume of extraocular muscles, significant improvement was observed postoperatively in patients with thyroidectomy and lymphadenectomy ($p<0.001$) compared to patients with thyroidectomy only ($p=0.2$) (4). Moreover, in this study (and the following studies also), a reduction of serum standard immunological parameters to undetectable titers was achieved in patients with lymphadenectomy. It is worth mentioning that, in a previous paper, the same authors reported a significant (but not complete) reduction of TS-Ab after subtotal thyroidectomy, allowing them to state that additional lymphadenectomy generated a drastic reduction of TS-Ab.

Preliminary results of our team showed an intense expression of TSH-receptors in the perithyroidal LN of the patients with GD and EO. This drove us to the assumption that cervical LN plays a significant role in retrobulbar immune processes. Moreover, the confirmed systematical isolation of activated PDC in the LN draining the thyroid and orbita supports our opinion that regional LN are involved in chronic stimulation of immune system, possibly by pleiotrofic effects. It is a known fact that PDC, after initial activation in peripheral blood (e.g. after viral infections), migrate in the LN and present antigens to both B- and T-cells. Immune response may also be augmented by regulation of T-cells. Systemic lupus is probably the most researched autoimmune disease in regard to the role of PDC, which congregate in the skin and generate the autoimmune effect. Therefore, it is a logical assumption that accumulation of PDC in the regional perithyroidal LN is involved in the pathogenesis of the GD. In the view of both literature and our data, we consider that regional LN play a major role in the induction and development of extrathyroidal antigens processing, persistence and autoimmune stimulation in the frame of GD autoimmune hyperthyroidism. For this reason, it is to be proved by further studies if additional cervical modified lymph node dissection should be a standard procedure in the treatment of GD, aiming to significantly improve the outcome of ocular disease.

MICRORNA-27A INHIBITS HEPATITIS C VIRUS REPLICATION

A study by Shirasaki *et al.* on microRNAs expressed in hepatitis B and hepatitis C virus - infected liver, found that miR-27a, which regulates lipid metabolism, is preferentially expressed in HCV-infected liver. miR-27a was found to repress the expression of lipid metabolism-related genes and ApoA1, ApoB100 and ApoE3, essential for production of viral infectious particles. Repression of miR-27a increased the cellular lipid content, viral replication and infectivity, while miR-27a overexpression decreased viral infectivity and enhanced in vitro interferon signaling. The study showed that patients who expressed high levels of miR-27a had a favorable response to pegylated IFN and ribavirin therapy. Expression of miR-27a is up-regulated by HCV infection and lipid overload, and in turn it represses HCV infection and lipid cell storage. The negative feedback contributes to the maintenance of a low viral load and can help the virus to escape the host immune surveillance and cause a persistent chronic infection (Shirasaki T, Honda M, Shimakami T, Horii R, Yamashita T, Sakai Y, *et al*. MicroRNA-27a regulates lipid metabolism and inhibits hepatitis C virus replication in human hepatoma cells. *J Virol*. 2013 Feb 28. [Epub ahead of print]).

MALIGNANT TUMORS OF DIGESTIVE ORGANS AND LIVER METASTASES AT THE TIME OF DIAGNOSIS (Abstract) **Aim:** Malignant tumors localized in the digestive tract have a tendency to local growth and invasion with lymph node metastasis. Distant metastases through blood with prevalent liver location are detected late in disease progression, in an advanced stage, when therapeutic possibilities are often limited to palliative therapy. **Material and methods:** The study included a series of 139 patients with liver metastases admitted to the Center of Gastroenterology and Hepatology Iasi between January 1 and October 10, 2011 for the identification of primitive tumor. The patients were investigated by endoscopy, imaging, laboratory tests including tumor markers. **Results:** At 99 of the patients (71%) we identified primitive digestive tumors, in 19 patients (13.6%) we found tumors with extradigestive location and in 21 patients (15%) the primitive tumor could not be identified. Primitive tumor was located in various segments of the digestive tract, liver, and pancreas was follows: esophagus 4 - (4%), eso-cardial-tuberositary 2 - (2%), eso-cardial-tuberositary with pancreatic invasion 1 - (1%), stomach 15 - (15%), ileocolon 1 - (1%), colon 19 - (19%), rectum 12 - (12%), liver, multicentric hepatolcellular carcinoma 23 - (23%) billiary tract - cholangiocarcinoma 2 (2%), pancreas 2 - (20%). In a series of 586 patients with malignant tumors of the digestive organs referred to the Iasi Oncology Outpatient Unit between January 1 and September 30, 2011, 132 patients (23%) had liver metastases at the time of diagnosis; the most common locations were the stomach 41% cases (42/119 patients), followed by the pancreas, 35%, and colon 31% patients (28/79 patients and 37/119 patients, respectively). Males were most affected, regardless of primitive tumor. **Conclusions**: Although diagnostic and therapeutic methods have made remarkable progress in recent years, these tumors, by their frequency and advanced stage at diagnosis, remain both an oncologic and public health problem mainly due to the limitations of curative treatment. **Keywords**: DIGESTIVE MALIGNANCIES, SYNCHRONOUS LIVER METASTASES, METACHRONOUS LIVER METASTASES, SMALL HEPATIC LESIONS.

In the last decades, progress in oncology explores both achievements and controversies in the management of malignant digestive tumors. There are continuous changes in

the management of digestive cancers, particularly of those with liver metastases at the time of diagnosis, which in the current debate on neoplastic disease approached at the level of molecular structures, receptors, genetic basis for diagnosis, and biologic therapy keep actual both the topic and its historical value with a role in comparing survival rates or validation of therapeutic success.

In gastroenterology, modern endoscopic techniques introduced and used in current practice, such as echoendoscopy, NBI (narrow band imaging), confocal endoscopy, magnification endoscopy, chromo-endoscopy, video capsule endoscopy, made possible the identification of malignant lesions in all stages of development, regardless of their location in the digestive tube, doubled by curative therapeutic interventions by endoscopic polypecteomy or mucosectomy of early stage neoplastic lesions (1).

However, epidemiological data collected worldwide (GLOBOCAN), in Europe (EUROCARE,), at national, regional, and local level contradict these assertions by the morbidity and mortality rates of advanced digestive cancer with metastases at the time of diagnosis (2, 3).

In this paper we discuss about the evolution of epidemiological trends of digestive cancer with liver metastases from statistical data to prognosis, presenting relevant data from reference studies and also data collected from the patients admitted to the Institute of Gastroenterology and Hepatology, Center of Gastroenterology and Hepatology, and Outpatient Oncology Unit, and particularities found in both research and practice.

Epidemiologically, the "geographic map" of digestive cancer with liver metastases at the time of diagnosis shows a worldwide distribution.

In the US, more than 59,000 patients are diagnosed annually with gastrointestinal tract cancer and liver metastases, and in a series of 150,000 new cases, 25% already had liver metastases and another 20-50% will subsequently develop metastases (4,5). In a meta-analysis of 1260 articles, the prevalence of liver metastases in patients with digestive cancer was found in almost half of the patients with esophageal, colorectal and stomach cancer (6), and the statistics using necropsy data show that incident and the deceased cases overlap (tab. I).

TABLE I
Frequency of digestive cancer with liver MTS. Necropsy studies

Initial diagnosis (%)	Autopsy (%)
Colorectal cancer 20 - 40	100
Esophageal cancer 50	100
Gastric cancer 12	100

Regionally, data centralized in 2001 (source: Iasi Oncology Office) on the frequency of cancer in the Iasi County show that digestive cancer with gastric and colorectal localization is among the most common cancers diagnosed in this geographic area (tab. II)(8).

In a study conducted at the Iasi Clinic of Gastroenterology and Hepatology in 2002 on a series of 119 patients with histological confirmed colorectal cancer with duble Dukes and TNM staging, in 80% of cases the diagnosis was made in a late stage (III and IV). The risk for tumor recurrence and the likelihood of micrometastases (M_x) not assessed by under staging, were poor prognostic factors for these patients, as confirmed by the low 1.6 year-survival rate in the subgroup of patients residing in Iasi town (tab. III) (9).

In 2010, a study conducted at the Iasi Institute of Gastroenterology and Hepatology on a series of 4282 patients evaluated by upper gastrointestinal endoscopy (UGE), 118 cases with malignant lesions (histological confirmed) have been identified, corresponding to a frequency of 2.75% of the endoscopically examined population.

TABLE II

Frequency of cancers according to location in Iaşi County

Cancer - location	**Year**				
	1997	**1998**	**1999**	**2000**	**2001**
bronchopulmonary	273	302	243	281	299
breast	171	164	181	154	174
gastric	**116**	**111**	**130**	**137**	**147**
uterine cervix	90	73	100	74	93
colon	**83**	**85**	**73**	**91**	**74**
bladder	81	60	49	54	55
prostate	77	74	63	53	43
pancreas	**76**	**72**	**75**	**76**	**79**
liver – billiary tract	**70**	**77**	**72**	**84**	**79**

TABLE III

Study series colorectal cancer: TNM/ Dukes staging

TNM stage	**No. cases (%)**	**Dukes stage**	**No. cases (%)**
I	2 - (1.7)	A	-
II	15 - (12.8)	B	5 - (4.2)
III	**25 - (21.3)**	**C**	**13 - (11.2)**
IV	**55 - (47)**	**D**	**2 - (1.7)**

In the interval January-October 2011, 139 patients with liver metastases (study series) were admitted to the Iasi Center of Gastroenterology and Hepatology for the identification of primary tumor. Following assessments by endoscopic methods, imaging – contrast ultrasound, CT, laboratory tests, tumor markers, etc., in 99 patients (71%) primitive digestive tumors and in 19 patients (13.6%) primitive extradigestive tumors were found. In 21 cases (15%) the primitive tumor remained unidentified.

The series of 586 patients with malignant tumors of the digestive organs recorded at the Iasi Outpatient Oncology Unit between January 1 to September 30, which overlaps almost entirely with the above mentioned series, drew attention on the fact that at the time of diagnosis one in four patients (132/586 patients - 23%) also had liver metastases: from a gastric tumor in 41% (42/119 patients), or pancreatic or colon cancer (35% -28/79 patients and 31% -37/119 patients, respectively). Males were prevalently affected regardless of primitive tumor location (tab. IV).

TABLE IV
Malignant tumors of digestive organs (C15-C26) and liver metastases

Malignant tumors	Total	with MTS	Male/Female
Esophagus	20		19/1
Gastric	119	42	83/36
Small intestine and duodenum	4	2	3/1
Colon	119	37	58/61
Rectum -sigmoid	22	5	10/12
Rectum	79	12	49/30
Anal canal	5	1	1/4
Liver	94		69/25
Gallbladder	16	3	6/10
Bile ducts	5	2	2/3
Pancreas	79	28	45/34
Liver MTS	24		15/9

In a WHO report on the countries with highest number of cancer cases, Romania ranks 47 of 50, with countries like Denmark, France, and USA occupying the first 10 positions (10). If we have in view that the diagnosis of cancer means an early stage but also an advanced stage tumor, interpreting the significance of the position in this classification, additional to the presented statistical data, changes the meaning of "position-based advantage" with "outcome nature" given by tumor stage at the time of diagnosis, i.e. late-stage with liver metastasis. Depending on the time of occurrence in relation to primary tumor, two categories of metastases can be distinguished: synchronous, occurring at the same time with the primary tumor or within the first two years after its resection (it is believed that metastases were already present at the time of resection), and metachronous, occurring after more than 2 years after primary tumor resection.

Metachronous metastases may occur after very long time. There are case reports of metastases occurring over 5 years after surgery, the longest interval being 9 years (11). A detailed management image, starting from the incidence of synchronous and metachronous liver metastasis to prognosis, is shown by the epidemiological studies using colorectal cancer as a model. Exemplifying on a French population (Burgundy, 25-year study period), with data collected from cancer registries, synchronous liver metastases were found in 14.5% cases (13,463 patients), while metachronous liver metastases following resection had a 1-year cumulative rate of 4.3% and a 5-year cumulative rate of 16.5%. The approximately eightfold increase in the frequency of liver MTS from stage I to stage III makes that stage at the time of diagnosis to be confirmed as important prognostic factor of increased relative risk (RR) for disease dissemination (tab. V) (12).

TABLE V
Relative risk (RR) for liver MTS frequency

TNM stage	Frequency of liver MTS (%)
Stage I	3.7
Stage II	13.3
Stage III	30.4

What are the therapeutic options in these patients? The evidence gathered so far are powerful arguments and justifications for unfavorable prognosis of these patients despite the combined therapeutic efforts (surgery, systemic or loco-regional chemotherapy, radiation, radio or cryoablation, etc.). Patients with distant metastases are generally not considered curable, palliative treatment being in many cases the only alternative (13). Unfortunately, even in colorectal cancer, where a considerable improvement in the prognosis of liver metastases was recorded, it is accepted that after a longer or shorter period, patients will die from disease recurrence or liver or systemic dissemination. Therefore, given the high incidence of metastases at presentation, guidelines to determine which patients should perform specific tests to identify them are essential.

Therapeutic management indicates that only 10% -15% of the patients with colorectal cancer and liver MTS undergo curative liver resection. Increasing the proportion of patients undergoing timely resection was more important for metachronous liver metastases (16.9%), and only 6.3% for synchronous liver metastases (tab. VII) (14, 15). Even though the main feature of metastasis from colorectal cancer is a relatively slow progression allowing a therapeutic approach that gives the patient a fairly good chance of survival compared with other metastatic cancers, significant therapeutic benefit is reported only in patients undergoing surgery, particularly curative. Also, chemotherapy in unresectable liver metastases from colorectal cancer is a palliative treatment, with poor long-term results given the low response rate not exceeding 20% (16) even though the proportion of patients treated with adjuvant chemotherapy and palliative care grew significantly and faster when synchronous liver metastases were present than in case of metachronous liver metastases.

Regarding the primary cancer, Manfredi draws attention on the ascending trend of palliative resection from 44.3% (1976-1980) to 63.7% (1996-2000) with an average of 60.7% of the cases, but without resection of liver metastases (12). Despite that, 5-year survival rate dropped dramatically regardless of the type of metastases, the differences found being possibly accounted for by local recurrence or systemic dissemination of disease (tab. VI) (16).

More promising approaches put their hope in more effective treatments and mass screening, but until then synchronous and metachronous liver metastases from CRC remain a considerable problem by their frequency and severity.

TABLE VI
Survival rate

Synchronous liver metastases	Metachronous liver metastases
•34.8% at one year •3.3% at 5 years	•37.6% at one year •6.1% at 5 years

This context justifies, based on evidence, the need for new strategies centered on shifting goals towards the early stages of digestive cancer by technological interventions in all cases with premalignant lesions or at risk for digestive cancer. Obviously, the aim is to approach cancer in a therapeutically curable stage, meaning its progression to be stopped by eradication or neutralization of the conditions that favor metastasis.

Benign or malignant in small liver lesion-associated digestive cancer? Another aspect frequently reported in digestive cancer patients is the presence of small liver lesions, the benign or malignant nature of which raises a series of issues, from clinical and morphological differences to diagnostic methods effectiveness. The wider use of staging investigations has further clarified the advantages of introducing new technologies in the diagnosis of cancer. Temporal trend analysis with supporting evidence on stage distribution, as well as temporal trends in survival in relation to the stage at diagnosis have generated an important concept – „stage migration" – which involves the intervention in this migration phenomenon of the new technologies (17, 18).

Thus, patients previously diagnosed with cancer in localized or regional stage are now diagnosed by imaging methods (CT, MRI) with advanced stage cancer. The likely outcome would be to remove low survival patients with previously undetected distant metastases from localized and regional cancers categories and to put them in the advanced cancers category. Therefore, an accurate staging at the time of diagnosis may improve survival rates but not stage progression since the early stage will lose cases surviving shorter than those remaining in this category, while the advanced stage will gain the cases surviving longer than those already in this category. However, Feinstein (1985) stated that overall survival would not change (19). The practical importance of this concept in terms of stage-appropriate therapeutic interventions should be kept in mind.

The clinical importance of using this conceptual model is also supported by the low frequency of small liver lesions (1 cm, <1 cm) reported in 12.7% of the patients, classified in 11.6% of cases as metastases from digestive cancer (colorectal cancer 22 %, stomach cancer 21%), lymphoma - 4% or breast cancer - 14%. Still unresolved remains the benign or malignant nature of the lesions as their histological confirmation is almost impossible because of small size up to 1 cm. The alternative is lesion-size monitoring by CT, MRI, ultrasound so that when an increase in size is detected a biopsy to be taken; time interval is on average 13 months (range 1-37 months). Without treatment, median survival is about 5-l0 months (20, 21). Prognosis is obviously better in patients with single metastases than in those with multiple metastases. In a literature series, 1-year survival was 5.7% in patients with diffuse metastases, compared to 27% in those with metastases in one lobe of liver, and 60% in those with single metastases. Median survival in patients with single metastasis was 25 months (22).

CONCLUSIONS

Despite remarkable progress in diagnostic and therapeutic methods in recent years, these tumors, by their frequency and advanced stage at the time of diagnosis, remains an oncology and public health problem, mainly due to the limitation of curative therapeutic possibilities.

THE EFFECT OF DISINFECTING SOLUTIONS ON THE DIMENSIONAL STABILITY OF DENTAL ALGINATE IMPRESSION MATERIALS

Disinfection of dental materials is necessary to avoid cross contamination with micro-organisms from blood and saliva. One of the available disinfecting methods is the immersion in disinfecting solutions. The main disadvantage of this method is the dimensional changes of the impression materials. Some studies suggest that alginate initially swells and then shrinks, while other studies suggest that alginate swell continuously with time. The situation is currently confused because there are many alginates commercially available and various disinfecting solutions. This study evaluated the dimensional changes of two commercial alginates (Blueprint Cremix and Hydrogum) in distilled water and two disinfecting solutions (Perform ID/sodium hypochlorite), using a traveling microscope, at 5 minutes intervals over a period of 1 hour. The samples were rectangular strips with thickness of 1.5 and 3 mm, respectively. In all cases, both alginates continuously shrank with time, in the three immersion liquids, indicating the transfer of water from the alginate into the disinfecting solution. The $t^{1/2}$ shrinkage plots were generally linear, but with an intercept on the $t^{1/2}$ axis, indicating the possibility of an initial expansion at very short times. In most cases, the ratio of slopes for both thickness were 1.33-1.54. Performed ID gave anomalous results for the 1.5 mm thick samples. At ten minutes the shrinkage was 1.34-1.72%, compared with -0.42% to 0.67% in the other two media. Shrinkage readings at 10 minutes showed much larger differences between 1.5 and 3 mm thickness for Perform ID compared with NaOCl and distilled water. It was suggested that the different behavior exhibited by Perform ID may be due to its higher osmolarity and its lower pH compared with NaOCl. The dependence of shrinkage rates on sample thickness could have clinical implications. An impression of a dentate mouth has an intricate structure with some parts of the impression being thinner than the others. Such regions could shrink more rapidly, indicating the possibility of distortion. The results suggest that manufacturer's guidelines for the time of immersion should be added to the technical info of these disinfectants, in order to minimize the dimensional changes and distortion of alginate impressions (Muzaffar D, Braden M, Parker S, Patel MP. The effect of disinfecting solutions on the dimensional stability of dental alginate impression materials. The effect of disinfecting solutions on the dimensional stability of dental alginate impression. *Dental Materials* 2012; 28: 749-745).

RARE TYPES OF DIABETES MELLITUS (Abstract): Diabetes mellitus is a heterogenous disorder characterized by chronic hyperglycemia and induced by a large number of etiopathogenic conditions. Beside type 1 and type 2 diabetes, which account for almost 90% of all cases, practitioners may encounter patients with more infrequent forms of diabetes, as those induced by mutations of a single gene, atypical immune disorders or neonatal diabetes. Monogenic diabetes is represented by genetic disorders in the structure of the β-cell (the MODY syndromes and the mutations of mitochondrial DNA) or in the insulin`s action (type A insulin resistance syndrome, Rabson-Mendenhall syndrome, leprechaunism, lipodystrophies). The rare forms of immune diabetes are determined by antibodies against insulin or insulin receptor or appear as a component of the "Stiff Man Syndrome". Neonatal diabetes is induced by mutations in genes that control β-cell development and function and may have a transient or permanent nature. Knowledge of the uncommon forms of diabetes mellitus enables physicians to apply the optimal treatment, to estimate the evolution of the patient and to apply a complete family screening in order to diagnose all other blood relatives as soon as possible. **Key words:** MONOGENIC DIABETES, INSULIN RESISTANCE, IMMUNE DIABETES, NEONATAL DIABETES.

Diabetes mellitus (DM) is a "syndrome" consisting of a heterogeneous group of disorders, with different etiology and pathogenesis, whose common element is hyperglycemia.

The prevalence of various types of diabetes differs significantly; type 2 DM is the most widely spread, followed by type 1 diabetes. The aim of this paper is to review some of the less common types of diabetes: genetic defects of the β cells, genetic defects in insulin action, some rare types of autoimmune diabetes and the neonatal DM.

1. GENETIC DEFECTS OF THE β CELLS

1.1. MODY Syndromes

In 1960, Fajans and Conn described for the first time a rare form of family inherited, non-insulin-dependent diabetes, occurring mostly in young non-obese Caucasians, with a good response to sulphonylureas. In 1964 Fajans suggested the name of "**M**aturity-**O**nset **D**iabetes of the **Y**oung" (MODY). In 1974 Tattersall published three MODY cases with autosomal dominant inheritance, while in 1975, together

with Fajans, he reported other 26 families with DM with autosomal dominant inheritance, going as far as 3-4 generations. Cases of MODY were identified afterwards on all continents; nowadays 7 types of MODY are described (1, 2).

The MODY syndromes represent 1% of all cases of DM and result from a single gene mutation (monogenic diabetes) which leads to dysfunctional insulin-producing pancreatic cells. The mutation is autosomal dominant inherited. The diabetes occurs in children and teenagers, usually before 25 years of age; although the disease starts during childhood, mild hyperglycemia causes the diagnosis to be delayed till older age. There is no tendency for ketosis.

The diagnosis criteria for MODY syndromes are (2):

1. Diabetes occurrence at a young age (at least one family member has to be diagnosed with DM below the age of 25)

2. There is no need for insulin treatment at least 5 years following the diagnosis;

3. Autosomal dominant inheritance (at least two generations of affected persons, although in most MODY affected families the disease is usually present in more than three generations)

As opposed to type 1 diabetes, MODY syndromes do not present a tendency for ketosis, the autoantibodies are absent (anti-insulin, anti β cell, anti-glutamic acid decarboxylase – anti-GAD) and there is no higher prevalence of HLA DR3 and DR4. As opposed to type 2 diabetes, MODY patients are usually thin, an insulin deficiency is present, but the insulin sensitivity is normal.

TABLE I
Classification of MODY syndromes (2)

Type	Mutant gene / protein
MODY1	Hepatocyte nuclear factor 4α (HNF 4α)
MODY2	Glucokinase
MODY3	Hepatocyte nuclear factor 1α (HNF 1α)
MODY4	Insulin promoter factor 1 (IPF 1)
MODY5	Hepatocyte nuclear factor 1β (HNF 1β)
MODY6	NEUROD1
MODY7	Preproinsulin

The seven MODY types (tab. I) can be grouped in two clinical forms: MODY induced by abnormalities of glucokinase (MODY2) and MODY induced by abnormalities of transcription factors (the remaining 6 forms).

1.1.1. Glucokinase MODY

Glucokinase is an enzyme that catalyses the phosphorylation of glucose to glucose-6-phosphate; in β-cells the glucose-6-phosphate acts as a glucose sensor, determining the regulation of insulin production

in accordance with the glycemic values. Over 200 mutations that lead to the *decrease of the glucokinase function* have been described. In the case of heterozygotes the glycemic level will be regulated at a higher level, but will remain under strict control. In homozygotes the insulin-dependent diabetes occurs in neonatal period (3). There are also mutations that cause an *increase of the glucokinase function*; these mutations cause congenital hyperinsulinism.

The patients present mild hyperglycemia even since birth (usually up to 145-150 mg/dl), these values slightly increasing with age. Postprandial glucose levels, as well as those measured two hours after glucose ingestion in the oral glucose tolerance test (OGTT), are just slightly higher than the fasting level (2, 3). An important increase in the glycemic level indicates that the patient develops type 1 or type 2 diabetes besides the mutation of the glucokinase gene. The value of HbA_{1c} is close to normal (values over 7.5% suggest another type of diabetes). Hyperglycemia is usually asymptomatic and the micro- and macroangiopathic complications of diabetes have an extremely rare occurrence. Differential diagnosis is made with type 1 and type 2 diabetes. As opposed to type 1 DM, in the case of MODY hyperglycemia remains slightly higher, anti β cells antibodies are absent, one of the parents has mild hyperglycemia and the C-peptide remains detectable. The differentiation from type 2 DM is more difficult, as both forms determine slightly higher glycemic levels and there is a family history of diabetes; in the case of MODY, obesity, as well as other insulin resistance markers are usually absent, the OGTT shows slightly higher values of the blood sugar level and hyperglycemia does not progress in time (3).

Due to the fact that the increase in the glycemic level is insignificant and complications are extremely rare, medications that would induce hypoglycemia are not recommended. If the patient is already under treatment, the medication may be ceased when the diagnosis of glucokinase MODY is confirmed. Medication should be stopped gradually, as MODY can also be associated with type 1 or type 2 diabetes (1, 3). Insulin therapy is recommended only during pregnancy, in order to improve the fasting hyperglycemia (4).

1.1.2. Transcription factor MODY

Transcription factors are proteins that bind to the DNA and form part of a complex regulation network that controls the gene expression. Most MODY patients show a heterozygote mutation in the gene of a transcription factor (most frequently the hepatocyte nuclear factors 1α and 4 α). The consequences of this mutation are: a decrease in the insulin secretion in the mature β-cells, a decrease in the development and multiplication of β-cells; apoptosis remains at the same level or is accelerated and the level of certain proteins involved in the carbohydrates metabolism (glucose transporters GLUT-2 or enzymes involved in the glucose mitochondrial metabolism) decreases (3, 5).

The patients are born with normal glucose tolerance; high blood sugar levels and diabetes occur gradually (between 10-30 years of age), as a consequence to the alteration of the β-cell function. The increase of the blood glucose level is age-related and the patients will need treatment (3). OGTT indicates very high glycemic levels two hours after glucose administration, although the fasting glucose levels are just slightly higher (usually under 150 mg/dl)

(3). Patients are usually thin and frequently develop the microvascular complications of diabetes. Besides these characteristics that are common for all types of transcription factors MODY, each type has its own extra-pancreatic manifestations:

MODY3 – Despite the high value of the HDL-cholesterol, the cardiovascular risk is significant (even higher than in the case of type 2 DM); the patients have a low renal threshold for glucose and glycosuria occurs (6, 7).

MODY1 – The patients have high birth weight (macrosomia). The risk of hypoglycemia is higher in the case of a MODY 1 infant (because of the more consistent insulin production *in utero* and during early childhood that eventually leads to a decline in insulin secretion and DM). Other characteristics are a decrease in the HDL-cholesterol values, lower levels of A1 and A2 lipoproteins and higher values of LDL-cholesterol (3, 6).

MODY5 – Renal impairment: renal cysts (66%), single kidney, horseshoe kidney, glomerulocystic kidney disease, renal cystic dysplasia; pancreatic hypoplasia with secondary exocrine dysfunction; low birth weight; genitourinary tract malformations (uterine anomalies, hypospadias); hyperuricemia and gout (3, 5).

As opposed to type 1 DM, in the case of transcription factor MODY one of the parents suffers from DM, the autoantibodies are absent at the time of diabetes diagnosis, ketosis is also absent even if patients do not receive insulin treatment, the C-peptide is detectable in plasma (>8 mmol/l) within 3-5 years following the diagnosis of diabetes, infants have a high birth weight and have a tendency for hypoglycemia, especially in the neonatal period (6). The differential diagnosis also includes type 2 DM; yet in the case of MODY the disease occurs during youth, there is a family history of DM at a young age, obesity, *acanthosis nigricans* or other markers of insulin resistance are usually absent, the lipid profile is characterized by an increase of the HDL-cholesterol, with normal or lower triglyceride values (uncommon for type 2 DM) while the sensitivity to sulphonylurea treatment is high (3, 6).

First intention treatment includes sulphonylurea drugs or prandial insulin releasers (repaglinide). Insulin therapy is considered only in the case of disease progression (7). Due to the high cardiovascular risk in these patients, statins are recommended for all subjects after the age of 40 (3).

1.2. Diabetes caused by mutations in the mitochondrial DNA

Mitochondrial DNA is a circular molecule that contains 37 maternally inherited genes. A punctiform mutation in position 3243 of the tRNA leucine gene (substitution of adenine for guanine) results in the occurrence of DM and sensorineural hearing loss. This type of diabetes remains frequently underdiagnosed. The mutation in position 3243 affects the mitochondrial respiratory chain, leading to cellular energy deficiency. The most frequently affected organs are the high metabolic activity ones: the pancreas, the cochleae, the retina (more seldom), the muscle, the kidney and the brain. The mitochondrial dysfunction in the pancreatic islets results in β-cells dysfunction, which involves the decrease of the β-cell mass and insulin deficiency (insulin sensitivity is usually normal). The mitochondrial DNA is maternally inherited, so that patients have a family history of diabetes in the maternal line; the children of a man carrying this mutation present no risk

of diabetes (8). Most mutation bearers show a high incidence of DM (over 85%) and sensorineural hearing loss (over 75%). Other clinical manifestations are less common: *retinitis pigmentosa*, cardiomyopathy, focal glomerulosclerosis, constipation or myopathy (9, 10).

The diagnosis is confirmed by testing the mutation in position 3243 in mitochondrial DNA in white cells or urine (9).

This type of diabetes requires early insulin treatment. Metformin is to be avoided (due to the risk of lactic acidosis), while coenzyme Q10 supplementation is recommended. The cardiac function must be monitored, especially for the patients with a family history of early cardiomyopathy. Aggressive antihypertensive medication is highly recommended, using inhibitors of angiotensin-converting enzyme in order to prevent renal complications (9). Any factors that would aggravate hearing impairment must be avoided, and ear infections must be treated promptly; when hearing loss occurs, auditory prosthetics and cochlear implants are recommended (3).

1.3. Other types of genetic defects of the β cells

Abnormalities of proinsulin to insulin conversion;

The production of mutant insulin molecules, resulting in an imperfect binding to insulin receptors.

These autosomal dominant inheritance types of diabetes are extremely rare, and their only manifestation is mild hyperglycemia (11).

2. GENETIC DEFECTS IN INSULIN ACTION

A defect in insulin action (or insulin resistance) occurs when a certain quantity of insulin produces a lower-than-usual biological response. The presence of *acanthosis nigricans* (skin indicator of severe insulin resistance) in a thin patient diagnosed with DM should point out to a genetic defect in insulin action (12).

Most often, genetic defects in insulin action are a result of ***mutations in the insulin receptor gene***. Three syndromes related to such mutations are usually described: type A insulin resistance syndrome, Rabson–Mendenhall syndrome and the Donohue syndrome (also known as Leprechaunism). The common characteristics of these syndromes are: hyperinsulinaemia, *acanthosis nigricans*, ovarian hyperandrogenism, glucose tolerance disorders (hypoglycemia and/or impaired glucose tolerance and DM) (13).

Type A insulin resistance syndrome is more common in females and has autosomal dominant inheritance. Patients are usually thin but present severe insulin resistance, *acanthosis nigricans*, signs of virilization (due to high levels of androgen hormones), hirsutism, oligomenorrhea, with frequent association of a polycystic ovarian syndrome (13). *Leprechaunism or the Donohue syndrome* was first described in 1954 by Donohue and Uchida and represents the most severe syndrome caused by the mutations in the insulin receptor gene. The patients present low birth weight, growth deficiency, glucose homeostasis disorders and specific dysmorphic features (large limbs, prominent ears, loss of subcutaneous fat, muscle atrophy, wrinkled skin and hypertrichosis, that make them resemble the Irish mythological Leprechauns (hence the name). The syndrome is characterized by autosomal dominant inheritance; death usually occurs before adulthood (3). *Rabson–Mendenhall syndrome* is also transmitted as an autosomal recessive trait. According to degree of insulin resistance

severity, it can be situated in between leprechaunism and the type A insulin resistance syndrome. Patients display *acanthosis nigricans*, severe growth retardation, dental abnormalities, coarse skin, senile facies, pineal hyperplasia, loss of subcutaneous fat, renal anomalies, abdominal distention and genitals enlargement. At the time of diagnosis patients may display paradoxical hypoglycemias which progress to diabetes. Life expectancy remains low (12, 13).

The clinical signs of these disorders are most often interrelated, and this is the reason for which some authors do not consider them as distinct syndromes, but rather as varied clinical traits of a *continuum* of the severity of the insulin receptor dysfunction (12).

As opposed to type 2 diabetics, patients with mutations in the insulin receptor gene are generally thin, although they display insulin resistance markers, high serum adiponectin levels and normal triglyceride values (14).

Insulin sensitizers (metformin, thiazolidinediones) have limited efficiency for this category of patients. When β-cell function diminishes, insulin therapy (in very high doses) is recommended (12). IGF-1 (*Insulin-like Growth Factor-1*) stimulates cellular glucose uptake and its storage as glycogen. In order to reduce side effects, IGF 1 can be administered together with the IGFBP-3 binding protein (15).

Hereditary lipodystrophies are clinically heterogeneous disorders characterized by loss of adipose tissue; they are associated with severe insulin resistance, DM, *acanthosis nigricans*, dyslipidemia and hepatic steatosis. Female patients can also display hyperandrogenism, oligomenorrhea and polycystic ovarian syndrome (3). There are two types of hereditary lipodystrophies: familial partial lipodystrophy and congenital generalized lipodystrophy.

Familial partial lipodystrophy is an autosomal dominant disease characterized by loss of peripheral adipose tissue from the subcutaneous compartment, associated with muscle hypertrophy, resulting in a "muscular" appearance of arms and lower limbs. Clinically, it is also characterized by loss of subcutaneous adipose tissue from the thorax and abdomen accompanied by an accumulation of adipose tissue in the face, neck and the intra-abdominal area. Diabetes frequently occurs over the course of the disease, especially in the case of female patients. Hypertriglyceridemia provides an explanation for the high incidence of cardiovascular mortality. The diagnosis is based on the "muscular" appearance of the limbs, loss of adipose tissue and diabetes occurrence at an early age in a non-obese patient with hypertriglyceridemia (3, 12).

Congenital generalized lipodystrophy (the Berardinelli-Seip syndrome) is an autosomal recessive disorder characterized by an extreme paucity of fat in the subcutaneous tissues even from birth, as well as by the "muscular" appearance described previously. Functional adipocytes are absent and consequently lipids are stored in metabolically active tissues. Patients display acromegaloid features, hypertrophic cardiomyopathy, intellectual deficits, hypertriglyceridemia, low HDL-cholesterol and hepatic steatosis which can lead to cirrhosis. Childhood growth is accelerated and diabetes appears during adolescence (3, 12).

Treatment for lipodystrophies includes dietary measures (very low content of lipids, less than 15% of total calories), intensification of physical exercise and medication: fibrates and high doses of fish oil for hypertriglyceridemia, metformin, thiazolidinediones and very high doses of insulin

for DM. Recent studies show that leptin administration improves the glycemic control, hypertriglyceridemia and hepatic steatosis (12, 13).

3. RARE TYPES OF IMMUNE DIABETES

Diabetes induced by anti-insulin antibodies: Anti-insulin antibodies may very rarely lead to an extreme decrease of insulinemia, so that they would determine the occurrence of DM.

Diabetes induced by anti-insulin receptor antibodies (type B insulin resistance) occurs in patients suffering from autoimmune diseases (the case of systemic lupus erythematosus, for instance). These patients frequently display *acanthosis nigricans.* The antibodies prevent insulin from binding to receptors at peripheral tissues level, causing hyperglycemia. In some cases, after binding to receptors, these antibodies react as insulin antagonists, leading to hypoglycemia.

Stiff Man Syndrome is a rare autoimmune disease of the central nervous system characterized by the stiffness of axial muscles, with painful spasms caused by unexpected stimuli or physical contact. High titres of anti-GAD antibodies are directed against an enzyme in the nervous system, and consequently the muscle is unable to relax (16). Anti-GAD antibodies also act upon the pancreas (which contains this specific enzyme), so that one third of the patients develop insulin dependent diabetes.

4. NEONATAL DIABETES MELLITUS occurs with a frequency of 1/300000 births up to 1/400000 births. It is the result of mutations of certain genes involved in the development and function of β-cells (17). About half of the cases have spontaneous remission (transient neonatal DM), while the remainder are considered to have permanent neonatal DM.

Permanent neonatal diabetes mellitus occurs most frequently (in about 50% of cases) due to mutation of genes encoding potassium channels (in 85% of cases the mutation arise spontaneously, while some cases are inherited in an autosomal dominant or recessive pattern); less frequently (about 12%) the insulin gene mutation is involved. The diabetes is usually diagnosed within the first 26 weeks of life and is characterized by severe hyperglycemia with ketosis. The C peptide is not detectable, and insular anti-cell antibodies are absent. Infants are smaller than gestational age (because of the reduced fetal insulin secretion) (17, 18). Because potassium channels are also found in the brain, the mutation of the gene encoding them may also determine neurological disorders (muscle weakness and epilepsy).

In the case of diabetes occurring due to mutations of genes encoding potassium levels, the initial treatment is insulin; in 90% of cases insulin can be replaced with sulfonylureas (in higher doses than those recommended for type 2 DM). Sulfonylureas might also improve the neurological symptoms. Diabetes caused by the mutation of the insulin gene requires insulin therapy.

Transient neonatal diabetes mellitus results from abnormalities in q24 region of chromosome 6. The disease occurs in the first week of life, with severe hyperglycemia and dehydration, yet without ketosis. The C-peptide is undetectable, the islet cell antibodies are absent. Newborn babies are smaller according to their gestational age (about 2.1 kg) and may present macroglossia and/or umbilical hernia. The insulin treatment is generally recommended for twelve weeks. In 50-60% of cases, diabetes reoccurs around the age of 14 (3, 18).

CONCLUSIONS

The accurate diagnosis of these types of diabetes can help define the prognosis, establish an efficient treatment and allow screening of patient's family members. Diagnostic testing is to be performed when the clinical picture is uncommon for type 1 or type 2 diabetes, when the anamnesis reveals an autosomal dominant inheritance, when certain characteristic traits of these rare types are detected as well as in all cases of diabetes diagnosed in the first six months of life.

CLINICAL-FUNCTIONAL EVOLUTION OF PATIENTS WITH ANKYLOSING SPONDYLITIS FOLLOWING PHYSIO-KINETOTHERAPHY (Abstract): Ankylosing spondylitis (AS), enigmatic from the etiologic point of view, appears with subjects who are still in school or involved in a productive activity. If detected in its early stages, under complex, constant and long-term treatment, patients have a good evolution. **Aims**: The objectives of the study are to describe the clinical and functional profile of patients with AS, sacroiliitis stage, and the evolution of physical and functional parameters under traditional physio-kinetotherapy. **Material and methods**: This retrospective study was performed on 40 patients with ankylosing spondylitis (AS), who were hospitalized in the Clinic of Rheumatology Iaşi, during 2008-1010, who satisfied the amended New York criteria for this. Subjects underwent an initial evaluation (first admission) and another one at the end of the study (second admission), after approximately 6 months. **Results**: The demographic characteristics, the clinical and functional elements of the study sample have indicated: the average age of 24.83 ± 3.948, predominantly male (82.5%) and 62.5% were from rural areas. Most cases occurred at the age of 19-25 (57.5%), beginning at 18-25 (77.5%), with an average of 19.60 ± 2.318. Following the radiological changes in the various stages of sacroiliitis, stage II prevailed (40%), then stage III (32.5%) and IV (15%). The evaluation of ASAS (Assessment of Spondylo Arthritis International Society) parameters and the respiratory system showed significant improvements of: BASDAI score with 31.53%, BASFI with 37.62%, BASMI with 20.66%, DIE % with 27.53 and of CV with 5.08% as well as a decrease in pain perception measured by VAS scale (p = 0.017). **Conclusions**: In the early stages of the disease, as far as the sample involved in the study is concerned, when the spine and vertebrae joints were not blocked by the evolution of the disease, corrective gymnastics and respiratory exercises, stretching and a good posture are very important, along with other therapies used to prevent axial ankylosis. **Key words**: ANKYLOSING SPONDYLITIS, SACROILIITIS, EVALUATION

Markerul diagnostic al spondilitei anchilozante (SA) este sacroiliita, leziune progresivă, cu patru stadii (Calin). Sacroiliita în marea majoritate a cazurilor este elementul de debut al bolii, manifestările clinice fiind marcate, de regulă, de simptome şi semne lombosacrate; ulterior procesul inflamator se extinde "în pată de ulei" la nivel axial exprimându-se prin lombalgii, dorsalgii de tip inflamator în 80% (1); această evoluție etapizată, trezeşte interesul şi dirijează terapia în direcția aplicării unor

modalităţi de prevenire a fenomenelor anchilozante la nivelul coloanei vertebrale, ce adiţional conduc şi la afectarea unor funcţii viscerale, precum cea pulmonară (2).

Enigmatică sub raport etiologic, SA debutează la subiecţii aflaţi încă în perioada activităţii şcolare sau productive. Depistaţi precoce, sub un tratament complex, insistent şi de lungă durată, bolnavii au o evoluţie favorabilă. Statisticile arată (3) că peste 60% din bolnavi pot duce în aceste condiţii, o viaţă normală, desfăşurându-şi întreaga activitate profesională; 35% - 40%, însă, dezvoltă infirmităţi prin afectarea coloanei vertebrale, cu sau fără prinderea centurilor, a articulaţiilor periferice (mai ales ale membrelor inferioare - 20-30%) şi fenomene viscerale. O analiză recent efectuată de Cochrane (4), concluzionează că fizioterapia (mai ales exerciţiul fizic) este benefică şi, în consecinţă, ea face parte integrantă din managementul SA; aplicarea unui program de exerciţiu fizic personalizat, în regim continuu susţine beneficiul terapeutic, mai ales în fazele precoce de boală.

Studiul nostru a avut două obiective majore: (i) evidenţierea profilului clinico-funcţional al bolnavului cu SA în stadiul de sacroiliită şi (ii) evoluţia parametrilor fizici şi funcţionali în urma aplicării fiziokinetoterapiei tradiţionale.

MATERIAL ŞI METODE

Am efectuat un studiu retrospectiv, prin monitorizarea foilor de observaţie la un lot de 40 de bolnavi cu SA, asistaţi în Clinica de Reumatologie Iaşi, în perioada 2008-2010. Criteriile pentru includerea în lotul de studiu au fost: pacienţi cu sacroiliită, fără afectare axială (clinic şi radiologic), care urmează tratament cu antiinflamatoare nesteroidiene (AINS) şi/sau biologice, fără comorbidităţi de tipul bronhopneumopatie obstructivă cronică (BPOC), diabet zaharat (DZ) dezechilibrat, ischemie coronariană silenţioasă, infarct miocardic, insuficienţă cardiacă sau angină pectorală de repaus sau la efort minim, sechele de rahitism, malformaţii congenitale toracice.

Fişa de evaluare standard, a înregistrat caracteristicile privind distribuţia pe grupuri de vârstă şi sex, după mediul de proveniență, tipul de debut, factorul ereditar, stadiul radiologic al sacroiliitei. Pentru definirea profilului clinico-funcţional al bolnavilor cu SA au fost evaluaţi o serie de indici de durere (VAS - *visual analogue scale*) şi mobilitate (indicii Ott, Schöber, distanţa deget-sol, diferenţa inspir/expir) precum şi scale valorice care au permis calcularea unor scoruri, atât iniţial (la prima internare) cât şi la finalul studiului (a doua internare), la interval de aproximativ 6 luni; au fost urmăriţi şi parametri ASAS (*Assessment of SpondyloArthritis International Society*) (5, 6) şi cel respirator (capacitatea vitală) (7, 2), ce permit evaluarea eficacităţii terapiei tradiţionale ce a fost efectuată instituţionalizat şi la domiciliu la recomandarea specialiştilor din cadrul spitalului şi sub îndrumarea unui cadru de specialitate de kinetoterapie.

REZULTATE ŞI DISCUŢII

1. Caracteristicile demografice ale lotului de studiu

Vârsta pacienţilor cuprinşi în studiu a variat între 18-31 ani, media înregistrată fiind de 24,83 ± 3,948, bărbaţii cu media de vârstă 24,94 ± 3,937 şi femeile cu 24,29 ± 4,271. Aceste valori, subliniază faptul că debutul bolii corespunde datelor din literatura de specialitate (1). În structura lotului, sexul masculin a predominat, 33 cazuri (82,5%) în acord cu datele care menţionează faptul că SA afectează îndeosebi sexul masculin.

Cele mai multe cazuri s-au înregistrat în intervalul de vârstă 19-25 ani (57,5%), urmat de categoria de vârstă 26-32 ani (40%) şi 18 ani (2,5%). Cei mai mulți pacienți (62,5%) au provenit din mediul rural.

2. Elemente clinice şi funcționale

Debutul tipic, s-a observat la vârsta 18-25 ani (77,5%) şi sub 18 ani (17,5%), cu o medie de 19,60 ± 2,318 ani.

Luând în considerare criteriile New York pentru diagnosticul SA (1), am remarcat predominant stadiul II (40%), urmat de III (32,5%), respectiv IV (15%).

Amprenta genetică a fost semnalată (20%) la 8 pacienți de sex masculin şi la 3 de sex feminin; antigenul HLA B27 a fost investigat la un număr redus de pacienți.

În funcție de scala analog vizuală de evaluare a durerii (VAS, 0 - 10 cm; 0 - absența durerii, 10 - durere maximă), am remarcat inițial ponderea semnificativ crescută a pacienților cu o percepție moderată (45%) – severă (40%), în timp ce la evaluarea finală, percepția durerii s-a mutat pe scală către o percepție a durerii uşoară (42%) – moderată (38%) (χ^2=8,20; GL=1; p=0,017). Aşadar, la cea de-a doua evaluare, se remarcă scăderea scorului VAS către o percepție uşoară la 61,1% din pacienții cu percepție moderată (11 / 18 cazuri) şi în proporție de 50% pacienții cu durere severă au scăzut pe scala VAS la durere moderată (8 / 16 cazuri) (tab. I).

TABELUL I

Evoluția percepției durerii în funcție de scorul VAS

VAS		a II-a evaluare									
		1	2	3	4	5	6	7	8	9	10
I evaluare	1										
	2	4									
	3	2									
	4		3								
	5			8							
	6				7						
	7					4					
	8						4				
	9							4			
	10								2	1	1

Durere uşoară scor între 1 şi 3	Durere moderată scor între 4 şi 6	Durere severă scor între 7 şi 10

Aplicând testul ANOVA asupra seriilor înregistrate pentru parametrii funcției fizice şi respiratorii pe parcursul monitorizării s-au constatat că valorile medii ai *indicelui Ott* şi *indicelui diferența inspir/expir (DIE)* (tab. II), au fost semnificativ crescute la reevaluare comparativ cu momentul inițial. *Indicele distanța deget-sol (DDS)* nu a prezentat diferențe semnificative, iar *indicele Schöber* a arătat că valorile medii au

fost semnificativ mai reduse (t=2,76; GL=78; p<0,l01). Valorile medii ale *capacității vitale (CV)*, au crescut uşor la reevaluare, dar nu semnificativ din punct de vedere statistic (t=1,79; GL=78; p>0,05) (tab. II).

TABELUL II

Indicatori statistici ai parametrilor funcționali şi respirator în funcție de momentul evaluării

Parametru	Eval.	Media	Min	Max	Dev.std	Err.std	Varianța	Mediana	p
Schöber (cm.)	I	3,56	1,5	3,5	0,79	0,12	4,69	2,5	**p<0,01**
	II	3,21	1,5	4,5	0,14	0,14	4,36	3,5	
DDS (cm.)	I	17,02	4	30	9,87	1,56	57,99	12	p>0,05
	II	14,13	4	30	9,15	1,45	65,22	11	
I.Ott (cm.)	I	1,99	0	3,5	0,95	0,15	47,73	2,5	**p<0,01**
	II	2,58	1,5	3,5	0,83	0,13	32,17	3,5	
DIE (cm.)	I	3,16	1	5	1,11	0,17	35,13	4,5	**p<0,00 1**
	II	4,03	2,5	6	1,16	0,18	28,57	4,5	
CV (%)	I	104,86	76	138	14,19	2,24	13,53	104,50	p>0,05
	II	110,19	87	138	12,43	1,96	11,28	109,30	

Evaluarea statistică a parametrilor ASAS, a permis aprecierea valorilor medii ale scalelor (9), ce măsoară nivelul de activitate al SA *(BASDAI)*, nivelul abilității funcționale a bolnavului *(BASFI)* şi nivelul mobilității spinale *(BASMI)*. Aplicând testul ANOVA asupra seriilor de valori înregistrate, pe parcursul monitorizării, s-a constatat că toate scalele au prezentat valori medii semnificative mai reduse la a II-a evaluare, la 6 luni, comparativ cu momentul inițial, ceea ce demonstrează o îmbunătățire a calității vieții pacienților cu SA (tab. III).

TABELUL III

Indicatori statistici pentru aprecierea statusului clinico - funcțional în funcție de momentul evaluării

Scala	Eval.	Media	Min	Max	Dev.std	Err.std	Varianța	Mediana	p
BASDAI	I	4,63	1	9	2,29	0,36	49,46	5,00	**p<0,002**
	II	3,17	1	7,9	1,77	0,28	55,84	3,15	
BASFI	I	34,15	4	82	22,07	3,49	64,63	32,0	**p<0,01**
	II	21,30	1	65	19,05	3,01	89,44	19,5	
BASMI	I	3,00	1	5	1,28	0,20	42,67	3	**p<0,05**
	II	2,38	1	5	1,21	0,19	50,84	2	

În ce priveşte consumul de antiinflamatoare nesteroidiene (AINS) şi medicația remisivă, modificatoare de boală DMARDs (*Disease Modifying Anti-Rheumatic Drugs*) nu au prezentat schimbări semnificative la cele două evaluări, pentru lotul studiat.

DISCUȚII

Spondilita anchilozantă are ca suport patogenic procesul inflamator ce se derulează la nivel sinovial (articulații sacroiliace) şi entezic (axial- coloana vertebrală şi periferic- inserțiile fascio-tendinose). Evoluția artritei sacroiliace se derulează în patru stadii ajungându-se la anchiloză (stadiul IV); la nivelul coloanei vertebrale procesul inflamator ascensionează treptat către regiunile înalte ale axisului, lăsând în urmă elemente care blochează sistemul vertebral transformându-l într-o tijă rigidă. Anchiloza articulațiilor interapofizare, costovertebrale şi sindesmofitele deteriorează nu numai mobilitatea axisului ci şi capacitatea respiratorie (1, 2, 8), fapt ce degradează suplimentar indicele de dizabilitate şi calitatea vieții bolnavului. Recunoaşterea bolii în stadiile incipiente ale evoluției sale, singura care poate asigura succesul terapeutic şi implicit un bun prognostic funcțional, depinde de interpretarea interactivă a manifestărilor clinice în contextul unor investigații complementare judicios alese (8).

În stadiile doar cu manifestări sacroiliace, în cazul lotului în studiu, când coloana vertebrală nu a fost blocată de evoluția ascendentă a bolii, fiziokinetoterapia tradițională a determinat evitarea limitării extinderii redorilor şi anchilozelor şi la îmbunătățirea tonusului muscular, necesar menținerii posturii şi a ventilației pulmonare (3).

Pornind de la ideea că o fiziokinetoterapie corectă şi insistentă, într-o fază în care morfologia coloanei nu este afectată (examen radiografic), este foarte utilă pacientului cu sacroiliită, studiul nostru a urmărit evoluția parametrilor clinico-funcționali şi respiratori în două momente situate la interval de 6 luni. Astfel, am constatat îmbunătățiri semnificative cu 29,64% a indicelui Ott, DIE cu 27,53%; a scorului BASDAI cu 31,53 %, BASFI cu 37,62%, BASMI cu 20,66%, iar a CV cu 5,08%, precum şi o scădere a percepției durerii înregistată prin scala VAS. Aşadar, valorile obținute, prelucrate statistic (Testul ANOVA, testul t-Student, Testul χ^2, coeficientul de variație) au demonstrat utilitatea programelor tradiționale de fiziokinetoterapie, în cadrul unui program terapeutic cu o metodologie modernă de susținere funcțională a coloanei vertebrale.

Metoda daneză Heckscher, alcătuită dintr-o suită de exerciții corectoare pentru toate segmentele posibil a fi implicate în actul respirator (10), sugerează că dubla disfuncționalitate din SA (coloana vertebrală şi aparatul respirator) pot deveni obiectivele unor programe speciale de kinetoterapie.

Capacitatea fizică, funcțională a aparatului locomotor şi respirator sunt astăzi cuantificabile prin structuri obiective, validate; evoluția morfologică a bolii, este şi ea cuantifiabilă prin imagistica tradițională şi modernă. Din schema terapeutică pentru SA a EULAR (*European League Against Rheumatism*) se desprinde clar locul fiziokinetoterapiei (5).

CONCLUZII

Din analiza datelor statistice a celor 40 de pacienți cu SA aflați în stadiul de sacroiliită (fără modificări vertebrale), s-a confirmat apariția bolii la vârsta tânără, cu predominanță la sexul masculin.

Îmbunătățirea parametrilor algici, fizici şi funcționali ai bolnavului, exprimată prin scale specifice pentru SA, a scos în evidență contribuția tratamentului complex, cu caracter multidisciplinar, în care cel kinetic, specific sistemului mioneuroartrokinetic, ocupă un loc principal.

În stadiile incipiente ale bolii, când coloana vertebrală şi articulațiile costoverte-

brale nu au fost blocate de evoluţia ascendentă a bolii, kinetoterapia prin mijloacele şi metodele ei, asuplizarea, posturarea sunt foarte importante, alături de celelalte terapii, pentru prevenirea disfuncţiei respiratorii.

NOUTĂŢI

DISFUNCŢIA DIASTOLICĂ ŞII MORTALITATEA ÎN SEPSISUL SEVER ŞI ŞOCUL SEPTIC

Disfuncţia sistolică a fost prima studiată în cazul şocului septic şi s-a constatat că nu întotdeauna determină agravarea prognosticului. Mai recent, a fost evaluată şi relaţia dintre disfuncţia diastolică şi riscul cadiovascular la pacienţii cu sepsis sever.262 pacienţi internaţi în unitatea de terapie intensivă cu diagnosticul de şoc septic au fost supuşi la 2 ecocardiografii succesive pe parcursul spitalizării, ei fiind evaluaţi şi din punct de vedere clinic şi al datelor de laborator. 36% dintre pacienţi au decedat pe parcursul spitalizării. Scăderea undei e' la nivelul inelului mitral a fost cel mai puternic predictor de mortalitate, şi după ajustarea datelor în funcţie de scăderea debitului urinar şi cardiac sau a saturaţiei oxigenului. Pacienţii cu disfuncţie sistolică şi/sau diastolică au avut creşteri uşoare ale troponinei T şi creşteri importante ale NT-proBNP. Aceste date susţin ideea că disfuncţia diastolică este frecventă şi este un predictor important de mortalitate în şocul septic. (Landesberg G, Gilon D et al. Diastolic dysfunction and mortality in severe sepsis and septic shock. *European Heart Journal 2012*; 33(7): 895-903)

DISABILITY ASSESSMENT TOOLS IN PSORIATIC ARTHRITIS: VICON GAIT ANALYSIS (Abstract) **Aim**: To evaluate health-related quality of life and disability in psoriatic arthritis (PsA) and to perform a complex biomechanical gait analysis in patients with PsA versus healthy controls. **Material and methods**: Preliminary prospective study on 33 consecutive PsA (2006 CASPAR criteria), with active multiple joint involvement disease. Assessments were done according to a predefined protocol and included: rheumatology- clinical evaluation and activity scores, dermatology- Psoriasis Area and Severity Index, PASI-score; functional disability- Health Assessment Questionnaire, HAQ, quality of life score- Short Form36, SF36; biomechanical gait analysis- tridimensional VICON MX optical motion capture system in PsA versus 33 age- and sex-matched healthy controls. *SPSS, EPI-INFO* and *MS EXCEL* were used for statistical analysis. **Results**: While the majority of PsA patients experienced a moderate impact on the quality of life as assessed by SF36 analysis, severe disease had major impact on their physical and emotional health status. The VICON gait analysis proved the statistical significant change ($p<0.05$) on several gait parameters as compared to controls, including: decreased range of motion for flexion/extension of the lower limbs joins and lower cadence, decreased walking speed and step length. Statistically significant correlations (Spearman, $p<0.05$) between changes in PsA gait parameters and SF36 results, but no association with HAQ ($p>0.05$) has been reported. **Conclusions**: The PsA burden is related to both quality of life and functional impairment. Severe changes in gait parameters are essentially reflected in SF36 analysis. **Key words**: PSORIATIC ARTHRITIS, DISABILITY, HEALTH-RELATED QUALITY OF LIFE, VICON GAIT ANALYSIS.

Artropatia Psoriazică (AP), entitate distinctă în cadrul reumatismelor inflamatorii cronice reprezintă o spondilartropatie prezentă la 4-30% din pacienţii diagnosticaţi cu psoriazis cutanat (1, 2, 3). Cu o distribuţie aproximativ egală pe sexe, AP implică atât scheletul axial-coloana vertebrală şi articulaţiile sacro-iliace cât şi scheletul periferic cu tendinţă la afectare asimetrică. Afectarea cutanată precede de obicei afectarea articulară care apare în medie la 10 ani după diagnosticul psoriazisului (4).

Evoluţia cronică, cu perioade de remisiune alternante cu acutizări, determină rapid eroziuni articulare, osteoformare, distrucţii şi anchiloze osoase cu impact

dizabilitant important asupra capacităţii funcţionale şi asupra calităţii vieţii, aspecte evidenţiate de multiple studii (5, 6, 7). Ambele componente ale bolii - cutanată şi articulară acţionează ca şi cumul de factori dizabilitanţi, potenţându-şi reciproc acţiunea.

Capacitatea AP de a genera handicap determină costuri socio-economice înalte, atât directe cât şi indirecte (7,8) similar altor patologii reumatismale considerate prototipuri de boli invalidante - poliartrita reumatoidă şi spondilita anchilozantă (9,10) şi justifică reconsiderarea algoritmului de diagnostic, monitorizare şi managementul terapeutic al AP.

Studiul îşi propune cuantificarea potenţialului dizabilitant al AP prin evaluarea impactului asupra calităţii vieţii, evaluare funcţională şi analiza biomecanică a mersului.

MATERIAL ŞI METODE

S-a realizat un studiu observaţional prospectiv pe un lot de 33 pacienţi spitalizaţi în Clinica de Reumatologie a Spitalului Clinic de Recuperare Iaşi, diagnosticaţi cu AP (criteriile Caspar 2006), cu forme poliarticulare, active de boală, cu implicarea articulaţiilor portante, în diferite stadii de evoluţie, fără alte comorbidităţi, pacienţi aflaţi sub tratament cu medicaţie remisivă *Disease-modifying antirheumatic drugs* (DMARDs) sau terapie biologică – blocanţi ai factorului α de necroză tumorală (a-TNFα).

Studiul a urmat un protocol predefinit care a cuprins cele două domenii respectiv: domeniul reumatologic (parametrii articulari individuali şi paraclinici de activitate ai bolii) şi domeniul dermatologic (evaluare clinică a implicării psoriazice prin scorul de activitate *Psoriasis Area and Severity Index* PASI). Pacienţii au fost evaluaţi funcţional prin chestionarul *Health Assessment Questionnaire* (HAQ), validat pentru AP (5). Impactul asupra calităţii vieţii a fost evidenţiat conform literaturii prin chestionarul *Short Form 36* (SF36). Chestionarul cuprinde 36 de întrebări grupate în opt domenii de interes: statusul fizic, starea de sănătate generală, capacitatea funcţională, durerea, statusul psihic, impactul social, impactul emoţional şi vitalitatea. SF36 oferă două scoruri finale: impactul bolii asupra componentei fizice şi impactul asupra componentei psihice (11, 12).

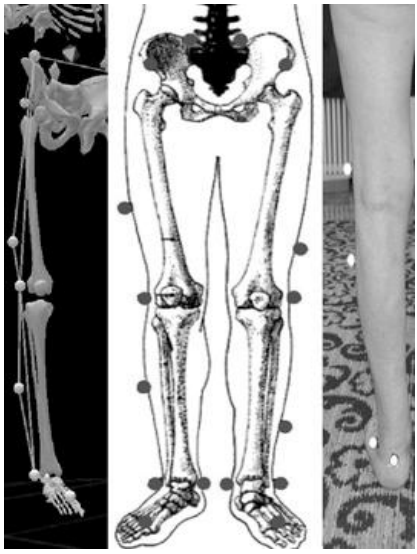

Fig. 1. Modelul *"plug in gait"* de aplicare a markerilor de suprafaţă

Evaluarea mersului s-a realizat cu un sistem optic de analiză tridimensională a mersului VICON (VICON Motion System Ltd., UK). Acesta presupune aplicarea a 16 markeri pasivi pe membrele inferioare ale subiectului care efectuează mai multe cicluri de mers. S-a utilizat modelul clinic predefinit de amplasare a markerilor "plug in gait" (13) (fig. 1). Şase camere de detec-

ţie în infraroşu au recompus prin triangulaţie în ”real time” poziţia spaţială a acestora. Dinamica a fost analizată de softul aparatului. S-au urmărit variabilele biometrice de timp şi spaţiu şi cinematica articulaţiilor coxofemurale şi genunchilor prin comparare cu un lot martor de 33 subiecţi sănătoşi similari pe criteriile vârstă şi sex.

Analiza statistică s-a realizat în programele MS EXCEL, EPI INFO şi SPSSS şi a cuprins analiză descriptivă şi testele: χ-*pătrat*, *t-Student* şi corelaţie Spearman.

REZULTATE

1. Particularităţile lotului: Lotul studiat a cuprins 33 pacienţi cu o repartiţie aproape egală pe sexe Bărbaţi:Femei = 1:1.06. Mediul de proveniență a fost predominant cel urban fapt explicat de accesul uşor la serviciile medicale ale acestei categorii U : R = 26 : 7. Majoritatea subiecţilor au avut nivel educaţional superior 63% - 21 cazuri. Media de vârstă la examinare a fost de 49 ani(32-57, $_{SD}$ 6,4), vârsta de debut fiind în medie de 40 ani (14-44, $_{SD}$8.1). Afectarea cutanată a precedat afectarea articulară în toate cazurile. Durata afectării cutanate a fost în medie de 15,2 ani (8-23, $_{SD}$ 5.8), durata de evoluţie a afectării articulare şi implicit durata AP fiind în medie de 7,5 ani(3-11, $_{SD}$ 2,8). Distribuţia formelor de boală a fost reprezentată de: forma axială 12 cazuri (36,36%), forma poliarticulară 20 cazuri (60,61%) şi un caz (3,03%) de artropatie mutilantă.

2. Domeniul reumatologic: Evaluarea clinică reumatologică a demonstrat forme active de boală cu implicarea unui număr mare de articulaţii tumefiate (NAT) şi articulaţii dureroase (NAD), gradul de activitatea al bolii fiind oglindit şi de tabloul paraclinic-sindrom inflamator prezent la majoritatea cazurilor (tab. I).S-a evidenţiat prezenţa dactilitei la 11 (33.3%) cazuri, eroziunile articulare fiind documetate radiologic la un număr de 19 (57,59%) cazuri; 28 (85%) pacienţi au fost sub terapie DMARDs, 5 (15%) pacienţi în tratament cu a-TNFα.

3. Domeniul dermatologic: S-a evaluat nivelul de activitate al leziunilor cutanate. Un număr de 12 (36,36%) cazuri au prezentat leziuni active cutanat. Scorul PASI a avut o medie de 1,79(1-25,5 $_{SD}$ 4,96); 1 caz cu psoriazis cutanat intens activ, 1 caz cu afectare moderată şi 10 cazuri cu afectare uşoară. S-a detectat afectare ungveală cu leziuni distructive la nivelul patului ungveal la 5(15,1%) pacienţi.

TABELUL I

Domeniul reumatologic: parametrii clinici şi paraclinici

NAD(0-78) medie	16.2 (6-24)
NAT (0-76) medie	**6.9 (3-12)**
Scala analogă vizuală a durerii VAS (0-100mm) medie	**60.48 (40-80)**
Starea de sănătate generală evaluată de pacient GHp (0-100) medie	**6.09 (4-8)**
Starea de sănătate generală evaluată de pacient GHd (0-100) medie	**6.33 (5-8)**
Viteza de sedimentare a hematiilor VSH (<15mm/h) medie	**28 (8-87)**
Proteina C Reactivă CRP (<0.5mg/dl) medie	**3.8 (0.6-12.8)**

4. Analiza capacităţii funcţionale şi a calităţii vieţii: Evaluarea prin chestionarul HAQ a relevat un impact funcţional important înregistrându-se o valoare medie de 1,62 (0,3-2,6 $_{SD}$ 0,61). Analizând pe grupe

de invaliditate s-a remarcat pentru afectarea severă o frecvenţă de 15,1%, afectare moderată prezentă la majoritatea cazurilor (54,5%) şi doar 10 pacienţi cu afectare funcţională uşoară. Scorurile înregistrate prin chestionarul SF36 au fost reorganizate în cele două domenii de evaluare: fizic şi mental. Dacă pentru domeniul mental s-a obţinut o medie de 41,63(15,7-58,4, $_{SD}$8.3), domeniul fizic a înregistrat o medie de 31,54 (20,7-53,6, $_{SD}$8,6). S-a pus în evidenţă, o corelaţie semnificativă statistic între rezultatele SF36 componenta mentală, SF36 componenta fizică şi HAQ :

SF 36 componenta mentală / HAQ r= 0.65, p <0.05 corelaţie Spearman

SF36 componenta fizică / HAQ r =0.64 p <0.05 corelaţie Spearman

5. *Analiza biomecanică a mersului*: Variabilele biometrice de timp şi spaţiu respectiv: viteza de mers (distanţa/timp), cadenţa/ ritmul paşilor (paşi / unitatea de timp), lungimea pasului (distanţa între două contacte succesive cu solul ale aceluiaşi talonului), dublu suport şi suport unipodal (fazele ciclului de mers cu spijin bipodal şi unipodal) au înregistrat valori semnificativ statistice mai mici pentru lotul cu AP faţă de populaţia sănătoasă. Raportul dintre sprijinul unipodal şi cel bipodal la pacientul cu AP atestă inversarea fazelor ciclului de mers, în sensul creşterii fazei de susţinere şi scurtării fazei de oscilaţie. Analiza cinematică s-a realizat prin calcularea intervalului dintre flexia şi extensia maximă în grade definit ca amplitudine de mers (*range of motion* - ROM) pentru articulaţiile portante. Compararea cu lotul martor a atestat valori semnificativ mai mici la pacienţii cu AP (tab. II, fig. 2).

TABELUL II

Variabile biometrice de timp şi spaţiu, date cinematice, analiză comparativă între cele 2 loturi

PARAMETRU	APs Medie DS	Lot control Medie DS	Diferenţa mediilor	Interval încredere diferenţa mediilor	p
Viteza (m/sec)	0,98 (DS 0,28)	1,28 (DS 0,14)	0,30	0,21-0,4	<0,05
Cadenţa (paşi/min)	99 (DS 12)	114 (DS 11)	15	12-18	<0,05
Lungime pas (m)	0,45 (DS 0,08)	0,64 (DS 0,04)	0,19	0,10-0,28	<0,05
Dublu suport (sec)	0,42 (DS 0,2)	0,23 (DS 0,3)	-0,19	-0,25 - -0,14	<0,05
Suport unipodal (sec)	0,49 (DS 0,05)	0,41 (DS 0,04)	-0,8	-1 - -0,6	<0,05
ROM (flx/ext) ŞOLD grade	36 (DS 7)	43 (DS 5)	7	2-8	<0,05
ROM (flx/ext) GENUNCHI grade	47 (DS 8)	56 (DS 3)	9	6-12	<0,05

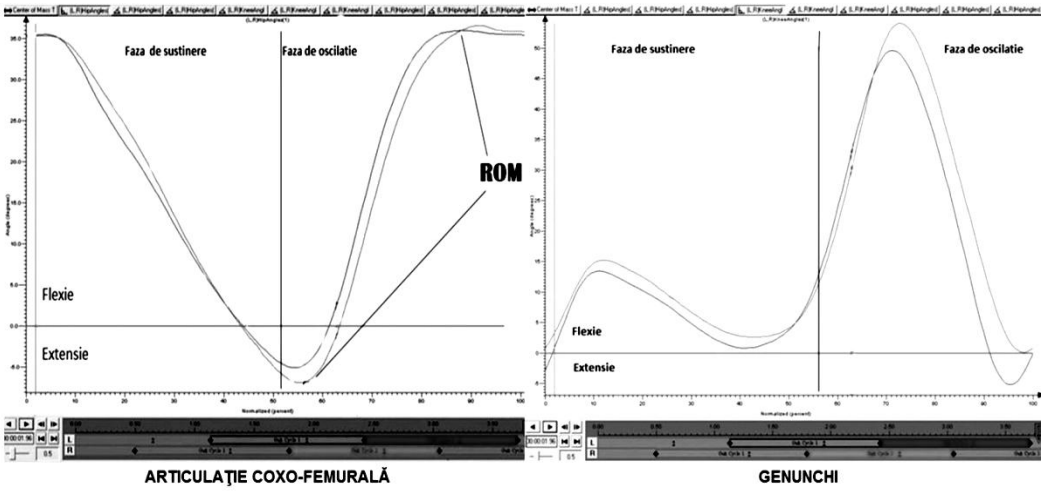

Fig. 2 Cinematica articulaţiilor coxo-femurale şi genunchilor

S-au comparat toţi parametrii de mers cu scorurile HAQ şi nu s-a pus în evidenţă o corelaţie semnificativă statistic (r în intervalul 0,28-0,32). Analiza acestora versus rezultatele SF36 a relevat o asociere semnificativă statistic (r în intervalul 0,59-0,62).

DISCUŢII

Rezultatele studiului atestă capacitatea invalidantă marcantă a AP la pacientul cu o evoluţie a bolii în medie sub 10 ani. Chestionarele HAQ şi SF36 s-au dovedit a fi instrumente valide în evaluarea statusului funcţional şi calităţii vieţii, mai mult, scorurile obţinute au fost în concordanţă cu cele din literatură (5, 6, 11, 12). Evaluarea biomecanică complexă a mersului a pus în evidenţă deficitul motor sever al pacientului cu AP faţă de populaţia sănătoasă. Analiza cinematică s-a corelat cu rezultatele obţinute prin SF36 dar nu şi cu HAQ. Acest aspect poate fi explicat prin faptul că deşi ambele chestionare analizează statusul funcţional global al pacientului, HAQ se concentrează mai mult asupra activităţilor realizate cu membrele superioare. Considerăm în acest sens utilă o analiză biomecanică globală pe un model cu markeri poziţionaţi pe corpul întreg într-un studiu ulterior. Absenţa implicării cutanate la majoritatea pacienţilor studiaţi nu se încadrează în profilul clasic al bolii ci a reprezentat un criteriu de selecţie pentru a pune în evidenţă impactul componentei articulare asupra calităţii vieţii.

CONCLUZII

Artropatia Psoriazică se poate prezenta sub forme invalidante de boală cu impact major asupra calităţii vieţii şi cu deficit funcţional sever al *pattern*-ului de mers atât pentru amplitudinea de mobilizare articulară cât şi pentru parametrii de mers aşa cum o demonstrează analiza VICON. Aceste modificări biomecanice se reflectă în gradele de disfuncţie obţinute prin scorurile SF36, dar o asociere cu evaluarea afectării funcţionale prin HAQ nu a putut fi pusă în evidenţă.

TRAUMATIC INJURIES CAUSED BY AIRBAGS (Abstract): The airbag is a passive life-saving system. In case of car crashes, the airbag inflates in milliseconds, activated by collision sensors and inflates with nitrogen. Since the airbag system became mandatory on automotive industry, the number of injuries associated with it has increased. A study performed by the National Automotive Sampling System (NASS) demonstrated that 66% of passengers suffer skin injuries from airbag. The airbag associated injuries rate is 42% at upper extremities, 41% at the face level, 3% at the neck level, 11% at the chest and abdomen level and 2% at lower extremities level. Though these wounds do not jeopardize the life, about 300000 car passengers suffer airbag related injuries in the USA. In this narrative review paper, we intend to review available literature data regarding airbag related trauma. We want to underline that despite the fact these systems are meant to protect life, they can be harmful or even deadly in certain circumstances. They can induce injuries on a broad range from easy to very dangerous when. **Keywords:** AIRBAG, AIRBAG RELATED TRAUMA.

The increase of the number of cars on the world's roads has brought about a significant increase in car accidents. In developed countries such as the USA and England, the effect has been felt even more strongly due to high accessibility to purchasing vehicles (1). Anyone can be injured because of a car accident either as a driver/car occupant or as a pedestrian. Many such cases have been occurring since the first airbags, so it was necessary to introduce measures for the protection of the road users, either punitive, legal or technological, represented by the belt-type safety systems or the airbag-type system. In the 1950s, the first functional airbag was reported on a car in the USA (1). The first to develop such equipment seems to have been Allen K. Breed. In 1968 he patented an accident and protection detection system. His interest was focused on military life-saving equipment. It was triggered based on sensors and filled with air. He sold his invention to Chrysler. In England, the first airbags were introduced in the late 1980s. Cars began to be extensively equipped with airbags in 1992 on Ford-built cars. In 1995, around 70% of the world's cars were equipped with airbags (1). Even though Breed's invention is a reference in the field of accident protection systems, attempts to patent a similar pro-

tection system have existed since the 1950s - apparently, John W. Hetrick, of Pennsylvania, applied for a patent in August 1952. In Europe, German Walter Linderer and American John Hendrik applied for airbag-related patents in 1951. Hetrick was the first to receive the patent, a few months before Linderer. Linderer's proposal contained a compressed air system that was triggered either by a shock in the car bumper bar, or by the driver.

Based on the information from the automotive industry, statistically, the airbag has saved and still saves lives daily. According to a US Department of Transportation report, between 1987 and 2015 alone, 44869 lives were saved (2). However, airbags seem to have the potential to cause serious and even fatal injuries (1, 3), especially in the case of children, fact made public around 1962. Tests performed by Ford in the Auto Safety Research Office have shown that there are enough forces associated to the airbag that can seriously injure a child. Tests conducted around 1980 continue to support the risk of injuries. Studies conducted over a period of about 40 years have shown that this system designed to protect car occupants can also kill (4, 5).

In 1990, the first reported case of airbag related trauma appeared when a 64-year-old woman died of chest injuries caused by the opening of an airbag. The year 1993 is an unfavorable year in the history of airbags, as the first cases of trauma in which the airbag opening caused the death of 23 children were reported. In 2000, the first fatal case associated with airbags was reported in England (1).

In 1995 appeared the side airbag, designed for lateral impact. In 2001, the knee airbag is launched on the market. The anti-slip (anti-submarine) airbag was designed in 2002, which is included in the seat's backside under the hump, to reduce the forward or backward movement of the basin. In 2005, a new improved dual-chamber airbag, specially created for the front seats, appeared. The two airbag compartments formed a depression in the center at triggering (6) and the "roll over" airbag (7).

In recent years, numerous deaths resulting from airbag injuries have been reported (8). Most accidents occurred at low speeds of the car, speeds at which harms would have not happen to passengers following an impact, no airbag inflates, only car damages. In the United States, NHTSA reported in 1999 146 deaths due to airbag related injuries, of which 84 children. All were front seat passengers. These passengers were either children or adults who were too close to the airbag, and following an impact, the airbag opened at a high speed, hitting the passengers straight in the face and causing, in almost all cases, skull fractures, lesions of the brain and neck blood vessels.

For this reason, it is advisable to keep an acceptable distance from the airbag, at least 20 cm, and to place children in the backseats is possible. At the time, airbags that are adjusted to suit the passenger's position, height and weight, with dual inflation system, which have considerably reduced the number of airbag related injuries, were developed (6).

American studies show that the most common injuries due to airbags are excoriations 64%, followed by contusions (38%), wounds (18%) and burns (8%) (9). The survival chance in car crashes increase if the airbags is doubled by the seat belts (10, 11). It also helps to reduce the risk of

serious injuries by distributing the forces resulting in the impact over the passenger's body.

The front airbags for the driver and front passenger are the most used, followed by the lateral ones for chest protection (12). The latest generation of airbags, already implemented on cars, are activated according to the severity of the collision. If the deceleration detected is below a certain threshold, then the bags are partially inflated. If it is a violent collision, the inflation is performed at full capacity.

The non-slip airbag working principle is like the other airbags. The anti-submarine pad, part of the non-slip bag, may or may not meet the passenger seat. A part of the bag inflates from below the chair or from under the board and hold the car occupants to slip under the steering wheel. At the impact time, it is filled with air limiting sliding or rotation of the pelvis (13).

The airbag device has the following components:

- the bag itself, made of a folded plastic fabric, with a volume of about 60 liters for the driver and 160 liters for the front passenger. Depending on the application, the area where the airbag is placed, the bulk bag volume varies between 30 and 200 liters.
- the cover that holds this bag

The opening of the device is triggered by shock-sensing sensors (which are piezoelectric systems) sensitive to decelerations that send the signal through the electrical contacts to a computerized control module then to the inflator module (electrical priming and gas generator system). If the airbag is activated, an explosive chemical reaction occurs (the most commonly used explosive is sodium azide) and the device is quickly inflated for the individual’s protection. The airbag opens in three phases that are the cutting (the airbag sac case is broken by a combustion material contained by a pyrotechnic device), the catapulting (the airbag is forced by the pressing from the cutting phase, to go out the steering wheel and inflates in about 0.04 seconds) and eventually the explosion (the airbag deflates almost immediately after the catapulting phase, while the gas escapes through special valves).

The lesions caused by the bag of the airbag device differ from those caused by the cover that holds the bag.

There are four types of collision mechanisms in car accidents, namely between the vehicle and other objects, between the vehicle occupant and the interior of the vehicle, between the internal organs and their cavities (the skull, the rib cage) and between the occupants of the vehicle and objects inside the car.

Airbag related injuries

Approximately 2.5% of drivers involved in car accidents suffer different types of airbag related injuries (14). Such lesions can occur at both high and low speed. Also, shorter people, closer to the airbag, can be more easily injured. The same situation includes children and the elderly, persons that could bot prepare the body for the impact, have slow reactions (takes usually longer time to figure out a way to protect in stress situations) (15, 16, 17).

Major types of airbag-related injuries include:

- disfigurement - hard pieces of the steering wheel or the airbag case hit the car occupants faces during the cutting process;
- chemical burns - the inflation gas used by the airbags might burn the face or the body skin when is not going out through

the evacuation valves but through arbitrary airbag crashes;

- fractures – the pressure of the body on the airbag could break upper body bones;
- pulmonary and cardiac complications;
- internal bleeding.

Anatomical formations most often affected by airbags are the face, the chest (exposed directly, closest to the front airbag), the neck (1), and the spine (18).

Lesions due to the cover cutting and bag catapulting

- atlanto-occipital dislocations;
- cervical spine fractures;
- cerebral trunk sections (19);
- cardiac, renal, splenic rupture (20, 21, 22);
- bilateral carotid internal dissection (23). Internal carotid artery lesions are accompanied by typical excoriations at the level of the neck, neurological sequelae, including hemiplegia, and a low Glasgow score, may be associated with a Horner sign (if the sympathetic chain is affected). Internal carotid artery lesions arise from the application of a force in the neck, in our case by the inflated airbag that determines a hyperextension that can cause the dissection of the artery at the junction between the intracranial portion considered immobile, and the extra cranial one, which is relatively mobile. If a patient has been the victim of a road accident involving an airbag, unilateral or bilateral carotid injury should be considered; contrast angiography should be performed if unilateral or bilateral carotid lesions are suspected (24);
- axonal lesions;
- subdural hematomas;
- facial injuries - fractures of the frontal sinus anterior wall, nasal bones, fractures or nasal septum dislocations, orbital wall fractures, temporomandibular joint contusions, dental lesions, breakage of dental prostheses, facial fractures in the form of cranial-facial disjunctions (rare). The airbag causes the temporomandibular joint to suffer, with pain, dislocation of jaw, chewing muscles and occlusion disorders (25).
- fractures of the cervical spine (of one or more vertebrae) by hyperextension;
- anterior and posterior longitudinal spinal ligaments injuries, medullary sections;
- ocular lesions (26), from palpebral hematomas with subconjunctival hemorrhage and corneal abrasions, to retinal detachment and eyeball rupture (27, 28), coexisting with chemical keratitis lesions (29). Other lesions cited in the literature include bullous keratopathy, hyphemia, iris sphincter ruptures, crystalline lens subluxations and dislocations, traumatic cataracts, hemophthalmias, some followed by a permanent decrease in visual acuity or even loss of vision. In the case of people wearing glasses, they break out producing wounds and corneal foreign bodies (30, 31, 32).
- ear lesions - various studies have shown that with the introduction of the side airbags the number of otology lesions associated with the opening of the airbag has increased. Otology lesions depend on the location of the airbag (side), the number of airbags (the more airbags that open, the higher the risk of suffering injuries), the car's interior volume, whether windows are open or not (studies carried out in this respect have shown that in all the cases where there were injuries the windows were closed) (**Error! Reference source not found.**);
- thoracic wall lesions - clavicle fracture, sternum fractures, rib fractures (33, 34, 35);

• open tibia fractures (36).

Lesions due to explosion (slapping)

The most common and frequent lesions are minor ecchymosis and excoriations located in the face, neck and upper limbs.

• chemical burns - chemical keratitis, contact dermatitis in the hands and face might happen when the airbag gas is touching the car occupant's skin depending on how sensitive their skin is to such contact. The children have more sensitive skin than the adults;

• barotrauma: the pressure inside the vehicle suddenly increases when the airbags are inflated. Typical lesions are eardrum perforation (usually unilateral) and bilateral barotraumatic pneumothorax;

• explosive noise with a detonation of over 170 dB can be associated with decreases in unilateral or bilateral auditory acuity, which is accompanied by persistent complaints and equilibrium disturbances;

• chemical pneumonia and asthma-related symptoms (sodium azide forms a white cloud inside the car);

• thermal, usually superficial burns in the hands, face, neck. They are caused by the action of hot gas generated when the airbag is inflated. Inhalation of hot gas can cause burns of the nasal mucosa, pharynx and larynx. The temperature outside of the bag after inflation reaches 80 degrees, sufficient to produce first and second degree burns after contact with the face, neck, and hands. A combination of chemical and thermal burns can cause necrosis of the entire skin layer (37, 38).

Lesions due to the airbag cover

• hands tegument detachment;

• injuries of the hands and forearms - pollex, metacarpal and phalangeal fractures, both bones of the forearm (sometimes bilateral), fingers and hands amputation (39). Open fractures showed severe lesions of muscle, tendons, synovial, vessels, nerves;

• cranial lesions - subdual hematomas, cortical contusions, cranial fractures, atlanto-occipital fractures;

• decapitations (4).

Other lesions

• premature rupture of membranes in a pregnant woman or fetal lesions (40);

• death, especially in children (6).

The spectrum of airbag specific lesions is broad enough to ask ourselves whether this equipment is lifesaving or not. However, from a statistical point of view, its utility has been confirmed, the number of saved lives justifying the use of this type of car accident protection equipment. The safety and security of both the persons inside the car and pedestrians, correlated with sufficiently consistent case studies of injuries caused by contact with airbags, has led to the development of a true industry oriented towards such systems. It has been required to use laboratory tests for safety systems to optimize them, on the one hand (41), also out of the need to reuse the same test equipment configuration in different scenarios. Virtual prototyping and laboratory tests on dummies currently precedes tests on deceased subjects used in car crashes self-controlled in laboratory conditions (42).

Two main potential cause groups of the airbag related injuries were identified. One is related to the airbag system malfunctioning meaning that either the airbag design itself has a technical issue or the system is old, and the maintenance process was not followed up and done properly. On the other hand, the car occupants should be aware that pieces of the airbag case flight

away during the inflate/deflate process, a gas at a certain amount of temperature might touch the car occupants body and burn the skin or just irritate it. Additional education during the driving school must include information about the potential harms the life-saving systems implemented into a car can produce. Even more, the persons with certain medical conditions, such as breathing issue or skin sensitivity should take precautions before driving.

CONCLUSIONS

With the decrease in the number of injuries resulting from road accidents, a new series of lesions, namely those caused by the car's safety systems, has emerged.

Safety systems demonstrated their value every day through the large number of lives saved and will always be one of the most important assets of a car.

Most experts say that an airbag is not advised for pregnant women, but to be as cautious as possible, the pregnant woman should move the seat as far back as possible to create a comfortable distance between her and the dashboard or between the wheel and her.

The solutions to avoid the potential lesions caused by the airbags include head restraint systems, modern safety belts with controlled, continuous tensioning features, intelligent airbags.

CARDIAC ARREST DUE TO VENTRICULAR FIBRILLATION IN A 23-YEAR-OLD WOMAN WITH BROKEN HEART SYNDROME

Broken heart syndrome, also known as takotsubo cardiomyopathy, is a syndrome characterized by a transient regional systolic dysfunction of the left ventricle associated to a psychological stress and therefore constitutes a form of stress cardiomyopathy. Patients with broken heart syndrome are most frequently women, presenting with chest pain and/or shortness of breath within hours or days of an emotional stress, frequently associated with electrocardiographic changes; elevation of markers of myocardial necrosis; large areas of akinetic myocardium involving circumferentially the apex, the base, or the midventricular segments in a noncoronary distribution, generally in the absence of obstructive coronary artery disease. As such, these patients are classically diagnosed with the broken heart syndrome while being evaluated for possible acute myocardial infarction. Less often, however, the diagnosis of broken heart syndrome is less obvious. The authors described the case of a 23-year-old female habitual marijuana user who was resuscitated after cardiac arrest and then diagnosed with midventricular stress cardiomyopathy complicated by subendocardial hemorrhage. They discussed this unique pathological finding, the incidence of arrhythmias in this syndrome, and the possible relation with chronic cannabis and tobacco use. Unfortunately, the patient did not survive, but had she survived, the management of the patient for secondary prevention would have been challenging considering the risk of recurrence with this disease. In conclusion, broken heart syndrome (acute cardiomyopathy due to emotional stress) may cause sudden death due to life-threatening ventricular arrhythmias as the presenting symptom in young women. This may be related to a more severe injury to the heart resulting in subendocardial hemorrhages and may be related to chronic tobacco and marijuana abuse. The optimal acute and long-term treatment of this severe form of stress cardiomyopathy remains unknown (Del Buono MG, O'Quinn MP, Garcia P, Gerszten E, Roberts C, Moeller FG. Cardiac arrest due to ventricular fibrillation in a 23-year-old woman with broken heart syndrome. *Cardiovascular Pathology* 201; 30: 78-81).

4. Clinica a II-a Pediatrie

LIVER INVOLVEMENT IN CELIAC DISEASE IN CHILDREN (Abstract): Celiac disease (CD) is an autoimmune systemic enteropathy triggered by gluten intake in patients with genetic susceptibility, characterized by clinic polymorphism: classic forms, mainly with digestive features, and atypical forms, liver involvement being a part of them. In present, any unknown cytolysis requires screening serologic determinations for CD. **Aims**: to assess the presence of liver manifestations in children diagnosed with CD, the outcome of liver function with gluten-free diet (GFD) and also to emphasize the importance of the immunological screening for CD in patients with unknown etiology liver dysfunctions. **Material and methods:** The trial was formed by 120 patients diagnosed with CD between January 2007 – December 2010 in 2nd and 3rd Pediatric Clinics of "Sf. Maria" Hospital Iaşi; liver function was assessed; there were determined viral hepatitis and autoimmune hepatitis markers; all patients were given GFD, hepatoprotective agents and antivirals specific to each form of hepatitis; the transaminases level variation was followed in time**. Results:** 12 of the CD diagnosed patients (10, 14%) had altered liver function at the onset of disease; the only abnormality was the increased transaminases level in 57, 14% of cases; HBsAg was found positive in 33, 33% (4 cases); liver biopsy in one patient evidenced steatosis. The study has shown that 4% of the patients with cryptogenetic hepatitis have a silent form of CD, the serologic screening for AGA, AEA, ATGA being essential for diagnosis. **Conclusions**: we have to rule out CD in patients with liver disease of unknown etiology, before we consider it as "cryptogenetic"; occurrence of cytolysis in the absence of positive viral markers requires the assessment of screening tests for CD. **Key words**: CELIAC DISEASE, ENTEROPATY, SCREENING SEROLOGIC, LIVER BIOPSY

Boala celiacă (BC) este o enteropatie sistemică autoimună declanşată de ingestia de gluten la pacienții cu predispoziție genetică caracterizată prin polimorfismul manifestărilor clinice: forme clasice, dominate de manifestările digestive şi forme atipice, afectarea hepatică fiind una dintre acestea. În prezent, orice sindrom de citoliză de etiologie neprecizată impune efectuarea testelor serologice de screening pentru BC (1, 2).

Scopul acestui studiu a fost de a evalua prezența manifestărilor hepatice la copiii diagnosticați cu BC. Obiectivele studiului au fost: stabilirea corelațiilor dintre gradul

sindromului de citoliză hepatică şi durata expunerii la gluten, spectrul manifestărilor extra-hepatice asociate şi evoluţia funcţiei hepatice sub regim fără gluten (RFG), precum şi evaluarea importanţei *screening*-ului imunologic pentru BC la pacienţii cu disfuncţii hepatice de etiologie necunoscută.

MATERIAL ŞI METODĂ

Lotul de studiu a cuprins 120 de pacienţi diagnosticaţi cu BC în perioada 1 ianuarie 2007-31 decembrie 2010 în Clinicile II şi III Pediatrie a Spitalului de Copii „Sfânta Maria" din Iaşi. La toţi pacienţii a fost investigată funcţia hepatică prin sindromul de citoliză, bilio-excretor, hepatopriv**,** γGT. În vederea stabilirii etiologiei hepatopatiei am determinat markerii virali – AgHBs, anticorpii (Ac) anti-VHC, anti-Toxoplasma, anti-Epstein Barr, anti-Citomegalovirus, markerii pentru hepatita autoimună. La toţi pacienţii s-a instituit RFG şi tratament hepatoprotector. Pacienţii cu AgHBs prezent au primit şi tratament antiviral specific formei de boală. După instituirea RFG a fost urmărită în dinamică evoluţia sindromului de citoliză.

REZULTATE

Din cei 121 de pacienţi diagnosticaţi cu BC, 10, 14% (12 pacienţi) au prezentat afectarea funcţiei hepatice la debutul bolii.

Vârsta pacienţilor a fost cuprinsă între 19 luni şi 127 luni (vârsta medie 88,5 luni). Repartiţia pe sexe: 7 pacienţi au fost de sex masculin şi 5 pacienţi de sex feminin (fig. 1).

TABELUL I

Valorile medii ale vârstei în relaţie cu sexul pacienţilor

Vârsta (luni)	**Media**	**-95%**	**+95%**	**Dev.std**	**varianţă**	**Er.std**	**Min**	**Max**
Feminin	48,333	-24,952	121,619	29,501	870,333	17,033	19	78
Masculin	61,600	2,359	120,841	47,711	2276,300	21,337	20	127
Total	**56,625**	**23,220**	**90,030**	**39,957**	**1596,554**	**14,127**	**19**	**127**

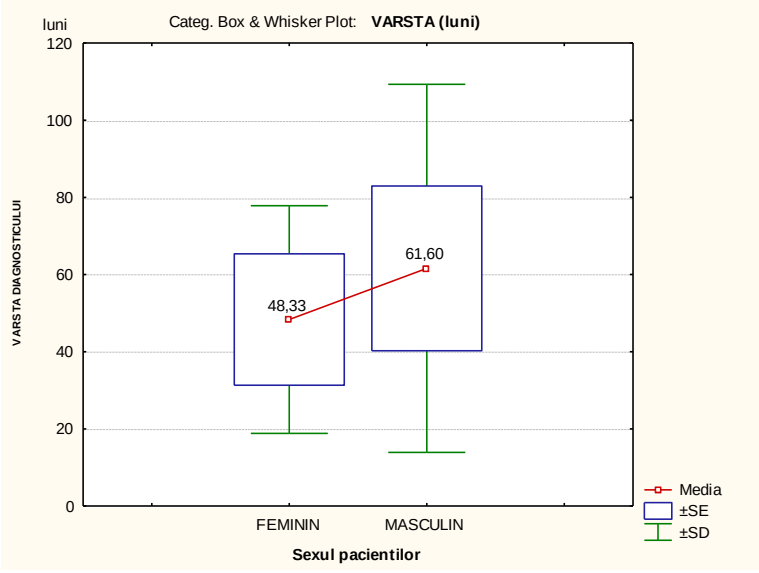

Fig. 1. Valorile medii ale vârstei în relaţie cu sexul pacienţilor

În studiul realizat am observat că nu există o corelație semnificativă statistic între durata expunerii la gluten (intervalul de timp dintre momentul debutului simptomatologiei și momentul diagnosticului BC) și apariția sindromului de citoliză (fig. 2).

	r Coeficient de corelație	p – nivel de semnificație
Interval timp vs. TGP	- 0.6191	0.102

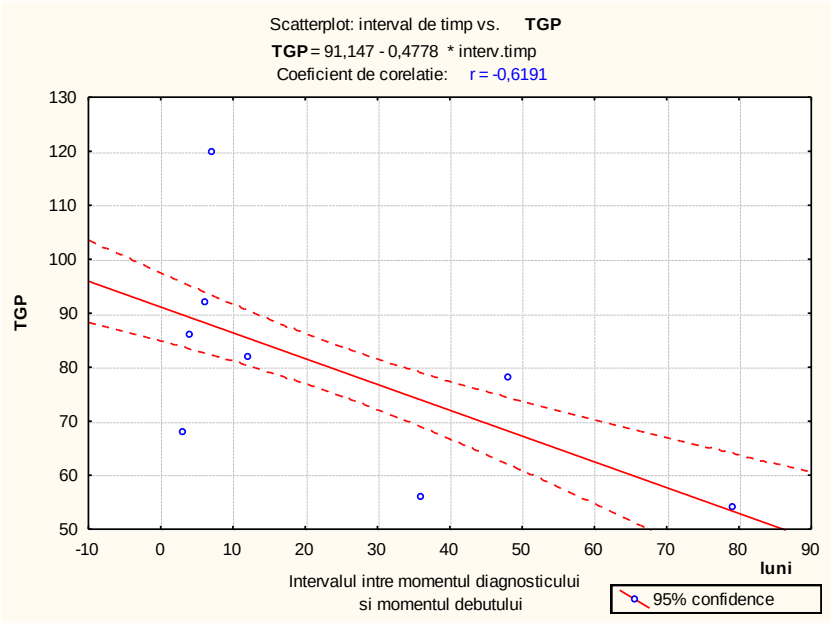

Fig. 2. Dreapta de regresie în corelația dintre intervalul de timp de expunere la gluten și TGP

Nu am întâlnit cazuri în care afectarea hepatică să fie singura manifestare a BC. Tabloul clinic la aceşti pacienți a cuprins: falimentul creşterii (100% cazuri), hepatomegalie (57,14% cazuri), dureri în hipocondrul drept (71,42% cazuri).

Analizând tipul afectării hepatice am observat că singura modificare a fost reprezentată de creşterea transaminazelor în 57,14% cazuri. Serologia pentru identificarea markerilor virali a evidențiat prezența AgHBs în 33,33% din cazuri (4 pacienți). Am observat valori mai mari de 3 ori valoarea normală a transaminazelor la pacienții cu hepatită cronică cu AgHBs (4,36% din cazuri). Fosfataza alcalină a avut valori crescute la un pacient cu nanism şi manifestări de osteoporoză.

Biopsia hepatică efectuată la un pacient a evidențiat prezența steatozei hepatice.

Evoluția transaminazelor după instituirea RFG poate fi observată în graficul 3.

La pacienții cu AgHBs absent s-a observat normalizarea sindromului de citoliză după introducerea RFG la 75% din pacienți (3 cazuri) după prima lună şi la 100% din cazuri după 3 luni de RFG (fig. 3).

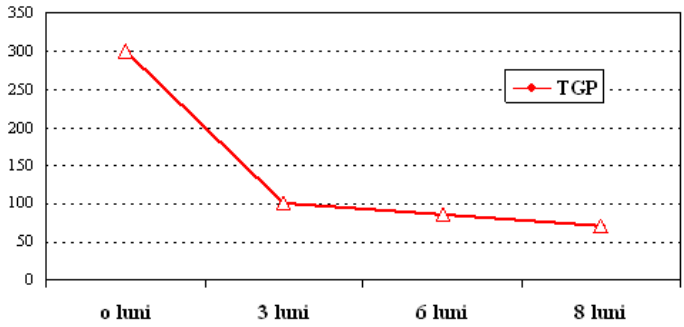

Fig. 3. Evoluția valorii medii a transaminazelor sub RFG

Pacienții cu AgHBs prezent au primit RFG şi tratament antiviral. După 3 luni de tratament transaminazele au revenit la valoarea normală în 2 cazuri. Într-un caz transaminazele s-au menținut la valori crescute după 6 luni de RFG. Clinic, pacientul prezenta persistența manifestărilor BC. Efectuarea biopsiei intestinale de control a evidențiat menținerea leziunilor intestinale de atrofie vilozitară, iar reluarea anamnezei a arătat nerespectarea RFG de către aceşti pacienți.

DISCUȚII

În ultimii ani s-au realizat progrese importante în cunoaşterea spectrului manifestărilor afectării hepatice din BC şi în înțelegerea patogeniei acestor modificări. În prezent se consideră că ficatul reprezintă una din „țintele" toxicității glutenului (3,4). Descoperirea mecanismului autoimun a BC a condus la asocierea sa cu alte boli autoimune, inclusiv cu hepatita autoimună (5,6). Utilizarea markerilor serologici anticorpi anti-gliadină, anti-endomisium, anti-transglutaminază tisulară permite descoperirea formelor atipice ale bolii, printre care şi hepatopatia din BC. Astfel, hipertransaminazemia izolată este recunoscută ca o posibilă formă de manifestare a BC şi poate fi expresia hepatitei „criptogenice" care se remite sub RFG.

În BC se cunosc trei tipuri de afectare hepatică: hepatita reactivă, hepatita cronică şi hepatita autoimună. În lotul studiat nu am întâlnit nici un caz de hepatită autoimună.

În studiul realizat de Bonamico şi colab. autorii au arătat că 54% din copiii cu BC au prezentat în momentul diagnosticului modificarea uşoară a funcției hepatice (creşterea transaminazelor) (1). Efectuarea biopsiei hepatice a evidențiat modificări histologice nespecifice: hiperplazia celulelor Kupffer, infiltrat celular mononuclear, steatoză şi fibroză uşoară (1, 4). Afectarea funcției şi arhitecturii hepatice la pacienții cu BC poate fi consecința unui proces autoimun (6, 7). Prima asociere dintre BC şi afectarea hepatică a fost descrisă în 1978 de Logan et al. (8).

Într-un studiu multicentric efectuat în Italia la copiii cu BC prevalența hepatitei autoimune a fost de 1,1%. Se discută despre rolul transglutaminazei tisulare în declanşarea procesului autoimun din diabetul zaharat, hepatita autoimună, tiroidita autoimună (9, 10). De asemenea, este cunoscut faptul că enteropatia produsă de BC determină malabsorbție şi creşterea permeabilității mucoasei intestinale, iar malnutriția se asociază cu disfuncția hepatică şi poate determina steatoză hepatică.

În prezent există controverse în ceea ce priveşte scăderea riscului de a dezvolta hepatită autoimună sub RFG (5). În studiul realizat hipertransaminazemia a apărut în toate cazurile în timpul expunerii la gluten . Datele din literatură arată rolul posibil al virusului hepatitic C ca trigger al reacției autoimune (6,9). La adultul cu hepatită cronică cu virus hepatitic C prevalența BC a fost de 1,2%. În studiul nostru nu am întâlnit decât asocierea cu virusul hepatitic B în 4,35% din cazuri.

Studiile efectuate au arătat că 4% din pacienții cu hepatită criptogenică prezintă forma silențioasă a BC, screening-ul serologic pentru anticorpii AAG, AAE, ATGt fiind esențial pentru stabilirea diagnosticului (10). Întotdeauna în *screening*-ul serologic trebuie utilizați anti-endomisium, anti-transglutaminază tisulară, valoarea predictivă pozitivă a anticorpilor anti-gliadină fiind redusă (6,8).

CONCLUZII

Investigarea funcției hepatice este obligatorie la toți pacienții cu BC în momentul diagnosticului, incidența sa în lotul studiat fiind de 10,14% din cazuri. Durata crescută de expunere la gluten nu s-a corelat cu apariția manifestărilor hepatice.

Este necesară excluderea BC la pacienții cu hepatopatie de etiologie necunoscută înainte de a fi considera "criptogenică". Prezența sindromului de citoliză în absența markerilor virali impune efectuarea testelor de screening pentru BC.

LIVER CIRRHOSIS - PROCOAGULANT STASIS (Abstract): Abnormal hemostasis tests and bleeding are often associated in liver cirrhosis. In these patients the balance between hypo- and hypercoagulation status is more fragile than in healthy people. In the hemostatic abnormalities associated with chronic liver disease are two main chategory factors: favoring hemorrage and favoring thrombosis. The main factors that favoring hemorrage are: low platelet count, impaired platelet function, decreased levels coagulation factors (II, V, VII, IX, X, XI), quantitative and qualitative abnormalities of fibrinogen, vitamin K defiency, low levels of trombin activable fibrinolisis inhibitor, activat plasminogenic tisular. The factors favoring thrombosis are elevated levels of factors VIII and von Willebrand, decreased levels of protein C, protein S, antithrombin, decreased levels of plasminogen. Traditionally it was thought that arterial and venous thrombosis is rare events in cirrhotic patients but recent studies have indicated that thrombotic complications can paradoxically occur even if clinically an increased risk of hemorrhage is considered. Treatment of venous thrombosis in patients with cirrhosis using routine anticoagulation with heparin and vitamin K antagonists has been described but with a high level of bleeding complications. So, based on the limited data available, AASLD guidelines stated no recommendations for or against the use of anticoagulation in cirrhotic patients with portal thrombosis. Although abnormal hemostasis tests and bleeding are often associated in patients with chronic liver disease it is a relatively poor correlation between hemorrhagic risk and routine diagnostic tests of hemostasis. Management of bleeding complications in liver cirrhosis varies and no general guidelines are available. The main therapeutic strategies are: red cell concentrate, plasma, platelet concentrate, recombinant factor VIIa, factor concentrates, desmopressin, antifibrynolitic agents, thrombopoietin receptor agonists, antibiotics. Clinical studies examining safety and efficacy of the various products for the different bleedeing or trombotic complications of liver cirrhosis need to be initiaded. **Key words**: LIVER CIRRHOSIS, BLEEDING, TROMBOSIS

Caz clinic. Pacienta MM, 54 de ani, din mediul rural s-a prezentat pentru episod de hemoragie digestivă superioară (hematemeză şi melenă). Pacienta este în evidenţa clinicii cu ciroză hepatică virală C decompensată vascular şi parenchimatos de aproximativ 5 ani şi este la primul episod hemoragic. Endoscopia digestivă superioară a evidenţiat varice esofagiene gradul IV cu stigmate de sângerare recen-

tă. Biologic s-a constat anemie uşoară, trombocitopenie (47 000/mm3), prelungirea timpului de protrombină şi a INR-ului. Ecografic s-a evidenţiat tromboză de venă portă; AFP în limite normale şi computer tomografia cu substanţă de contrast nu au identificat elemente sugestive pentru hepatocarcinom. Această situaţie pe care o întâlnim relativ frecvent în practica clinică ilustrează paradoxul anomaliilor de hemostază la pacienţii cu ciroză hepatică: pe de o parte statusul hemoragic (hemoragie digestivă superioară cu scăderea numărului de trombocite, reducerea indicelui de protrombină, creşterea INR – ului) şi pe de altă parte statusul procoagulant exprimat prin tromboză. Care este terapia optimă la un astfel de pacient, dacă medicaţia anticoagulantă este indicată sau nu, rămân întrebări la care datele din literatura actuală nu pot da un răspuns cert.

În ultimii ani viziunea clasică asupra tulburărilor hemostazei din ciroza hepatică s-a modificat semnificativ, cu implicaţii majore atât fiziopatologice cât şi de conduită terapeutică.

Ficatul este locul de sinteză atât al factorilor coagulării cât şi a inhibitorilor lor, cu excepţia factorului von Willebrand (fvW). Având în vedere acest lucru, afectarea hepatică prin boli cronice determină alterarea coagulării, direct proporţional cu scăderea rezervei funcţionale hepatice.

Hemostaza în ciroza hepatică este într-un echilibru fragil între procesele protrombotice şi cele antitrombotice. Cunoaşterea acestor mecanisme care influenţează permanent echilibrul între factorii care favorizează hemoragia şi respectiv tromboza, determină o mai bună înţelegere a fiziopatologiei alterărilor hemostazei în ciroza hepatică şi are multiple aplicaţii terapeutice.

Alterările hemostazei în ciroza hepatică

Trombocitopenia severă şi defectele trombocitare

Anomaliile de număr şi funcţie ale trombocitelor sunt obişnuite în evoluţia bolilor cronice hepatice. Aproximativ 1/3 din pacienţii cu boală cronică hepatică au trombocitopenie (70 000 – 90 000/mm3) care progresează odată cu evoluţia bolii (1).

Trombocitopenia în ciroza hepatică are mecanisme multiple (2,3):

- splenomegalie;
- sechestrare hepatică şi splenică;
- supresie medulară (evidentă în hepatita acută virală C, abuzul de alcool, deficitul de folaţi);
- scăderea producţiei de trombopoietină (funcţia de sinteză a ficatului este absolut necesară pentru producerea de trombocite via trombopoietină - care reglează producţia de plachete în măduvă);
- medicaţie imunsupresoare.

Alterările funcţionale trombocitare sunt consecinţa unor mecanisme multiple (4):

- deficitul sintezei de tromboxan A2;
- deficienţe de stocaj;
- anomalii ale glicoproteinei trombocitare 1b.

1. Scăderea nivelelor factorilor II, V, VII, IX, X, XI, XII

Ficatul este locul de sinteză al fibrinogenului şi al factorilor II, V, VII, IX, X, XI, XII. Factorul von Willebrand (fvW) nu este sintetizat în ficat, ci în endoteliu. Concentraţia plasmatică a fvW este crescută în insuficienţa hepatică acută datorită creşterii sintezei ca proteină de fază acută (răspuns la injuria tisulară) şi secundar injuriei endoteliale, consecinţă a endotoxinemiei.

Factorul VIII este sintetizat în principal de ficat dar şi extrahepatic de celulele endoteliale şi sinusoidale, astfel încât nive-

lul factorului VIII nu descreşte cu agravarea bolii hepatice; nivelul său poate fi chiar crescut întrucât de multe ori boala hepatică asociază inflamaţia. Factorul VIII este crescut în insuficienţa hepatică fulminantă şi scade în coagularea intravasculară diseminată.

3. Vitamina K este cofactor esenţial în producţia de forme biologice active de factori ai coagulării II, VII, IX, X. Alterarea γ carboxilării datorată deficienţei sau antagonismului vitaminei K determină sinteză de precursori inerţi cunoscuţi ca proteine induse de absenţa vitaminei K – PIVKA (Proteins Induced by Vitamine K Absence) care sunt eliberaţi în sânge. Semnificaţia acestor precursori nu este încă clară (1).

4. Fibrinogenul plasmatic în majoritatea cazurilor este normal sau crescut în bolile hepatice cronice. Scăderea fibrinogenului sub 100 mg/dl se întâlneşte în bolile cronice hepatice severe. Fibrinogenul crescut din hepatitele cronice, icterele colestatice, hepatocarcinom este în mare măsură un fibrinogen non-funcţional în 60-70% din cazuri, care are lanţuri alfa şi conţinut crescut de acid sialic, datorită creşterii activităţii sialil transferazei în hepatocitele imature generate în timpul injuriei hepatice. Fibrinogenul scade pe măsură ce boala progresează până la disfibrinogenemie.

5. Alterările sistemului fibrinolitic. Toate proteinele implicate în fibrinoliză cu excepţia tPA şi PAI1 sunt sintetizate în ficat. În ciroza hepatică scad nivelurile de (5):

- plasminogen
- alfa2antiplasmină
- glicoproteină bogată în histidină
- factorul XIII
- trombin activable fibrinolisis inhibitor (TAFI).

Hiperfibrinoliza se corelează cu severitatea disfuncţiei hepatice evaluată prin scorul Child Pough (6).

6. Antitrombina III *(AT III)* este glicoproteină non-vitamina K dependentă sintetizată de ficat şi endoteliu. În bolile hepatice cronice este scăzută datorită reducerii sintezei şi/sau creşterii consumului prin hiperfibrinoliză. Suplereea de ATIII nu corectează fibrinoliza la pacientul cu ciroză hepatică.

7. Plasminogenul leagă fibrina de cheag, iar fibrinoliza este activată prin conversia plasminogenului prin acţiunea tAP (activat plasminogenic tisular) în plasmina; inhibitorul 1 al activatorului plasminogenului este crescut (PAI1). Acesta inhibă tAP şi acest lucru determină o stare de hiperfibrinoliză.

8. Proteina C şi proteina S sunt glicoproteine dependente de vitamina K şi sunt sintetizate în principal în ficat. În afecţiunile hepatice acute sau cronice concentraţia lor scade concomitent cu alţi factori ai coagulării dar nu sub 20%.

Aşadar factorii care favorizează hemoragia în ciroza hepatică sunt: trombocitopenia, anomaliile funcţionale trombocitare, scăderea concentraţiei plasmatice a factorilor de coagulare (II, V, VII, IX, X, XI), anomaliile cantitative şi calitative ale fibrinogenului, nivelurile scăzute de alfa2 antiplasmină, TAFI, tPA în timp ce factorii procoagulanţi sunt: niveluri crescute de fvW şi factor VIII, scăderea proteinei C, proteinei S, antitrombinei, plasminogenului (1).

Semnificaţia prognostică şi evaluarea riscului hemoragic în ciroza hepatică

În general nivelul factorilor de coagulare reprezintă un indicator al funcţiei de sinteză hepatică. Timpul de protrombină face parte din parametrii care indică gradul insuficienţei hepatice conform clasificării

Child Pugh, iar INR-ul este inclus în scorul MELD. Determinarea fiecărui factor de coagulare în parte nu aduce foarte multe informaţii suplimentare. Analiza multivariată a factorilor de prognostic în ciroza hepatică arată că factorul VII este factor independent de predicţie asupra supravieţuirii: factorul VII < 34% este predictiv pentru mortalitate în 93% din cazuri (7).

Pe de altă parte nivelul testelor globale de coagulare nu are valoare predictivă pentru riscul de sângerare (8). În prezent datorită dificultăţilor, inclusiv financiare, în evaluarea activităţii pro şi anticoagulante rolul factorilor coagulării este greu de estimat. Balanţa coagulării în bolile cronice hepatice nu este stabilă comparativ cu subiecţii fără boală hepatică. În consecinţă ea poate fi perturbată, în special dacă coexistă condiţii patologice precipitante care acţionează ca zone trigger: efracţia variceală, infecţiile, insuficienţa renală. Consensul privind hipertensiunea portala (Baveno V) statueaza faptul ca timpul de protrombina/INR-ul nu reprezinta un indicator al statusului coagularii la pacientul cirotic (9).

Trombocitopenia este un marker indirect al prezenţei varicelor eso-gastrice (diametrul splinei/numărul de trombocite se corelează cu prezenţa varicelor) dar nu are valoare prognostică în ceea ce priveşte sângererea variceală sau de la alte nivele. Valoarea trombocitelor se poate corela în schimb cu pierderile de sânge din intervenţiile chirurgicale (10).

Sângerarea prin efracţie variceală în CH este consecinţa hipertensiunii portale. Sunt studii care arată care arată că sângerarea variceală se însoţeşte de anomalii de hemostază mult mai frecvent comparativ cu pacienţii care nu au sângerat. Semnele endoscopice de „nipple" ca marker al sângerării variceale sugerează un rol limitat dar existent al hemostazei la acest nivel.

În timpul procedurilor minim invazive (toracenteză, paracenteză, puncţie lombară) nu există ghiduri care să prevadă valorile optime ale testelor de hemostază, nici tratamentul profilactic sau curativ (11).

Puncţia biopsie hepatică poate fi făcută fără suport de trombocite începând cu valoarea trombocitelor de peste 60 000/mm3; dacă riscul hemoragic este crescut se recomandă realizarea procedurii transjugular.

Trombozele în ciroza hepatică

Clasic se consideră că pacienţii cirotici ar fi protejaţi de tromboze, datorită statusului lor „autoanticoagulant". Date recente din literatură au indicat că tromboza venoasă poate apare la pacienţii cu ciroză hepatică chiar în condiţiile profilaxiei medicamentoase (12).

Hipercoagulabilitatea din CH poate fi sintetic exprimată prin triada Virchoff:

- flux scăzut
- vasculopatie asociată statusului cronic inflamator
- scăderea proteinelor anticoagulante: C, S, antitrombină.

Complicaţiile trombotice pot fi la nivel portal, mezenteric, pe venele hepatice sau periferice, în extremităţi, asociate cu embolii pulmonare.

Tromboza de venă portă

Tromboza de venă portă (TVP) are o prevalenţă între 0.6 şi 26%, funcţiede caracteristicile lotului studiat cât şi de modalitatea de diagnostic (13).

Se cunoaşte că pacienţii cu TVP au evoluţie mai rapidă şi mai gravă (14). Factorii favorizanţi cunoscuţi şi acceptaţi ai TVP sunt (15):

- sexul masculin
- chirurgia anterioară sau tratament intervenţional al HTP

- sângerare anterioară variceală
- scăderea nr de trombocite
- insuficienţa hepatică avansată.

Alături de aceşti factori cunoscuţi în TVP de dată recentă sunt introduşi alţi 2 factori (16):

- mutaţia 20210A a protrombinei
- scăderea sub 15 cm/s a velocităţii fluxului portal măsurat prin ultrasonografie Doppler.

Velocitatea este invers proporţională cu scorul Child Pough: cu cât este mai mică cu atât insuficienţa hepatică este mai severă; sub 10 cm/s poate fi considerată, după unele cercetări factor de risc independent a supravieţuirii (17).

Pentru a avea o concluzie unanim acceptată sunt necesare în continuare studii care să ateste unanim toate aceste date.

Tromboza acută de portă

Este factor de prognostic negativ la pacientul cirotic, atât pentru mortalitate cât şi pentru resângerarea variceală imediată (18).

Diagnosticul de tromboză recentă sau "acută" de portă este dificil şi se poate pune în două situaţii (19-21):

- dacă în urmă cu 60-90 de zile pacientul a avut explorare imagistică negativă pantru acest diagnostic sau
- în cazul simptomelor clinice sugestive pentru acest diagnostic: dureri în etajul abdominal superior, febră, ascită instalata brusc, sângerare variceală etc.

În tromboza acută de portă cercetarile recente recomandă asocierea de activator al plasminogenului tisular cu heparină cu greutate moleculară mică.

Sub acţiunea activatorului plasminogenului tisular, plasminogenul se transformă în plasmină. Are actiune litică numai locală (spre deosebire de urokinază şi streptokinază care induc stare litică sistemică), timp de înjumătaţire de o oră şi 30 minute, cu eliminare a 80% din cantitate în mai putin de 10 minute - ceea ce permite întoarcerea la statusul coagulant anterior. Activatorul plasminogenului tisular se administrează în perfuzie continuă (Actylize – fiole de 20mg sau 50 mg, cu injectomat, 0,025mg/kgc/zi). Totuşi consensul privind hipertensiunea portală (Baveno V) afirmă că, în momentul de faţă, nu sunt suficiente evidenţe pentru a recomanda tromboliza locală în trombozele portale (9).

Heparina cu greutate moleculară mică se administrează subcutanat în funcţie de greutatea corporală: 0,5mlx2/zi la o greutate corporală între 50-59 kg; 0,6 pentru greutate de 60-69 kg şi 0,9 la o greutate peste 90 kg.

Tratamentul se adminstrează 4-7 zile. Pe tot parcursul tratamentului pacienţii sunt monitorizaţi initial şi la fiecare 48 de ore biochimic (INR, fibrinogen, D-dimeri, antitrombina III) şi imagistic. Rezultatele pot fi: remisie completă, parţială sau lipsă de răspuns (22).

Tromboza de arteră hepatică. După transplant hepatic apare mai frecvent la cei care au avut pretransplant TVP, ceea ce denotă o stare de hipercoagulabilitate la aceşti pacienţi (23).

Tromboza ca factor de progresie a fibrozei. S-a observat, în primul rând experimental, prezenţa de microtrombi în vascularizaţia hepatică din ariile de fibroză. Cu alte cuvinte, activarea coagulării în aria vasculară apare ca răspuns la fibroză, determinând extinderea acesteia ca răspuns la ischemie (24).

Tromboza în steatohepatita nonalcoolică. Ciroza hepatică secundară steatohepatitei nonalcoolice (NASH) este în mod particular asociată cu anomalii ale hemostazei ce favorizează statusul protrombotic: nivele crescute de PAI 1, fvW, factor VII,

fibrinogen, precum şi hiperagregabilitate trombocitară şi disfuncţie endotelială (25).

Indicaţii terapeutice

Indicaţiile terapeutice în hemoragiile din CH

În ciuda progreselor efectuate în înţelegerea perturbărilor hemostazei la pacienţii cu ciroză hepatică, tratamentul hemoragiilor nu este standardizat. Intervenţiile terapeutice au ca scop principal oprirea sângerării şi mai puţin corectarea tulburărilor de coagulare.

Administrarea de masă eritrocitară poate fi salvatoare în caz de anemie severă, îmbunătăţeşte funcţia plachetară dar are numeroase efecte nedorite (26).

Plasma înlocuieşte atât pro cât şi anticoagulanţii dar poate prezenta reacţii alergice (1%) precum şi efecte hemodinamice nedorite, la fel ca transfuziile de sânge sau masă eritrocitară (creşterea hipertensiunii portale şi a riscului de sângerare, injurie pulmonară, sindrom circulator de supraîncărcare) (27).

Concentratul plachetar îmbunătăţeşte hemostaza primară; s-a demonstrat o producere adecvată a trombinei la valori peste 50 000/mm3; are efecte secundare similare transfuziilor (28).

Concentratele de factori procoagulanţi au, comparativ cu plasma, avantajul administrării unui volum mic cu concentraţie crescută, ceea ce evită supraîncărcarea volemică. Nu au fost testate în studii randomizate şi, teoretic, au risc de tromboză.

Factorul recombinant VII normalizează timpul de protrombină dar nu şi-a dovedit eficienţa în hemoragia variceală sau în cea secundară intervenţiilor chirurgicale şi este trombogenic (29)

Desmopresina (analog de hormon antidiuretic) îmbunătăţeşte hemostaza primară dar scade eficienţa terlipresinei (30).

Agenţii antifibrinolitici – aprotinina şi acidul tranexamic scad pierderile de sânge în timpul transplantului hepatic. Nu au fost testaţi în sângerarea variceală sau postchirurgicală.

Agoniştii receptorilor de trombopoietină (Eltrombopagul), prin analogie cu hepatita cu virus C, creşte numărul de trombocite (31).

Antibioticele. Până la 2/3 dintre pacienţii cu ciroză hepatică prezintă infecţie activă cu stare de hipocoagulabilitate (dovedită prin trombelastogramă). Administrarea la aceştia de antibiotice scade riscul sângerării, îmbunătăţeşte coagularea şi hemodinamica.

Tratamentul trombozei venose în ciroza hepatică.

Teoretic, ar trebui folosite anticoagulante cu greutate moleculară mică, heparină, antagonişti ai vitaminei K. Complicaţiile care apar în aceste situaţii sunt grave şi numeroase - în 83% din cazuri (32). Mai mult, heparina necesită antitrombină pentru a-şi exercita rolul anticoagulant, iar nivelul antitrombinei este scăzut la aceşti pacienţi.

Folosirea antagoniştilor vitaminei K este şi aceasta dificilă întrucât nu este stabilit un nivel - ţintă pentru INR şi timpul de protrombină (a căror valori de altfel variază între diferite laboratoare).

Conform ghidului AASLD, în TVP la pacienţii cu ciroză hepatică, nu există recomandări ferme, pro sau contra, pentru folosirea de anticoagulante. Sunt necesare studii viitoare care să certifice eficacitatea anticoagulantelor în aceste situaţii.

CONCLUZIE

Coagulopatia pacientului cirotic, cu echilibrul său fragil între factorii procoagulanţi şi cei hemoragici, rămâne încă o provocare pentru medicul practician. Cel mai

recent consens privind hipertensiunea portală (Baveno V) certifică faptul că, pe baza datelor actuale, nu pot fi efectuate recomandari practice privind managementul acestor pacienţi (9). Noile direcţii de cercetare propuse de Baveno V includ nevoile de corectare a tulburărilor de coagulare în ciroza hepatică, precum şi evaluarea semnificaţiei prognostice a coagulopatiei şi trombocitopeniei.

NOUTĂȚI

MODULAREA EXPRESIEI GENELOR DE VIRULENȚĂ ALE *STAPHYLOCOCCUS AUREUS* DE CĂTRE ANTIBIOTICE BETA-LACTAMICE UTILIZATE ÎN CONCENTRAȚII SUBINHIBITORII

Stimularea expresiei genelor de virulenţă de către concentraţii subinhibitorii ale anumitor antibiotice poate modifica evoluţia infecţiei şi poate face ca terapia antimicrobiană să devină ineficientă. Investigarea efectelor concentraţiilor subinhibitorii ale antibioticelor care inhibă sinteza peretelui bacterian asupra expresiei genelor de virulenţă şi asupra producerii biofilmului la *Staphylococcus aureus* a fost realizată folosind metode difuzimetrice şi prin real time PCR cantitativ. Expresia genelor *spa* (*staphylococcal protein* A) şi *luk*E a fost stimulată de concentraţii subinhibitorii de penicilină şi cefalotin, în timp ce expresia *agr* RNAIII (*accessory gene regulator*) nu a fost afectată. De asemenea, s-a observat producerea unui biofilm mai dens în prezenţa unor concentraţii subinhibitorii de cefalotin. Subrt N, Mesak LR, Davies J. Modulation of virulence gene expression by cell wall active antibiotics in *Staphylococcus aureus*. *J Antimicrob Chemother* 2011; 66: 979-84.

PERITONITA BACTERIANĂ SPONTANĂ: COMPLICAȚIE SEVERĂ A CIROZEI HEPATICE – STUDIU PROSPECTIV

Gabriela Balan, Anca Trifan, D. Botezatu, Carmen Anton, Camelia Cojocariu
Universitatea de Medicină şi Farmacie „Gr. T. Popa”
Facultatea de Medicină
Institutul de Gastroenterologie şi Hepatologie Iaşi

SPONTANEOUS BACTERIAL PERITONITIS: SEVERE COMPLICATION OF LIVER CIRRHOSIS (Abstract): **Aim:** To evaluate the prevalence, incidence, pathogens, and clinical outcome of the patients with liver cirrhosis and spontaneous bacterial peritonitis (SBP). **Material and methods:** Prospective study of 34 episodes of SBP occurring in 29 patients (mean age was 56,89±8,79 years) with cirrhosis and ascites admitted to hospital. The diagnosis of SBP was made by a polymorphonuclear cell count in ascitic fluid of >250 cells/mm^3 in the absence of data suggestive of secondary peritonitis. **Results:** In our series SBP occurred more frequently in men, 21 of 29 patients (72,41%). Microorganisms were isolated in 12 episodes (35,29%): gram-negative bacteria in 8 (66,67%), and Gram-positive in 4 (33,33%). The first-line treatment failure and in-hospital mortality rates were 26,47% and 17,64%, respectively. The low in-hospital mortality seems to be related to earlier diagnosis and treatment. In the multivariate analysis, three significant independent predictive factors of in-hospital mortality were identified: a high Model of End-Stage Liver Disease (MELD) score, renal failure, and SBP caused by extended-spectrum β-lactamase-producing organisms. The relapse rate of BSP was 21,73%. **Conclusions:** SBP remains a serious complication, especially in patients with a high MELD score. Ceftazidim represents a good choice in empirical treatment of SBP. **Key words:** LIVER CIRRHOSIS, PERITONITIS, TREATMENT, PROGNOSIS

Termenul de peritonită bacteriană spontană (PBS) a fost introdus în 1971 de către Conn şi Fessel, PBS fiind definită ca infecția spontană a lichidului ascitic în absența identificării oricărei surse infecțioase intraabdominale (1).

Ciroza hepatică (CH) se caracterizează printr-o susceptibilitate crescută la infecții datorită deficiențelor mecanismelor de apărare ale organismului. PBS este cea mai frecventă infecție la bolnavii cirotici, urmată de infecțiile tractului urinar (20%), pneumonie (15%) şi bacteriemie (12%) (2). Recunoscută ca o complicație frecventă şi severă, PBS apare la 8-27% din pacienții cirotici cu ascită spitalizați (3).

Supraviețuirea acestor bolnavi depinde de precocitatea diagnosticului şi tratamentului şi de instituirea profilaxiei secundare a PBS. Având în vedere că PBS poate evolua asimptomatic sau insidios, se recomandă efectuarea paracentezei diagnostice în toate cazurile de CH cu ascită şi când apar manifestări clinice sugestive precum durerile abdominale, febra, encefalopatia hepatică, agravarea disfuncției renale sau hepa-

tice (4). Prezența în lichidul de ascită a peste 250 neutrofile/mm^3 semnifică supra-infecția bacteriană a acestuia (PBS).

Tratamentul antibiotic empiric trebuie început imediat ce diagnosticul a fost stabilit, înainte de a se cunoaşte agentul etiologic şi sensibilitatea *in vitro* (4). Bacteriile cel mai frecvent identificate în 65% din cazurile cu culturi pozitive sunt bacteriile Gram-negative din familia *Enterobacteriaceae*, în special *Escherichia coli* şi *Klebsiella pneumoniae*. Restul agenților microbieni sunt reprezentați de cocii Gram-pozitivi (5). Cefalosporinele de generația a III-a (cefotaxim, ceftriaxona, ceftazidim) şi combinația amoxicilină-acid clavulanic, reprezintă antibioticele de primă intenție în tratamentul PBS.

Prognosticul pe termen lung al bolnavilor cu PBS este nefavorabil. Rata recurenței PBS în primul an este de 40-70%, iar supraviețuirea la 1 an şi la 2 ani, după un episod de PBS este de aproximativ 30-40%, respectiv 20% şi chiar mai scăzută la pacienții cu scor Child-Pugh peste 10 (6). Profilaxia PBS este indicată la următoarele 3 categorii de pacienți cirotici: antecedentele de PBS, bolnavii spitalizați pentru hemoragie digestivă superioară şi cei cu conținut scăzut de proteine în lichidul de ascită. Utilizarea pe termen lung a antibioticelor cu spectru larg poate determina creşterea numărului microorganismelor rezistente la antibiotice cu implicații considerabile asupra managementului şi tratamentului PBS, conducând la necesitatea reevaluării ghidurilor terapeutice actuale (6).

Scopul studiului prezent de a evalua trăsăturile clinice şi prognosticul bolnavilor cu ciroză hepatică complicată cu PBS internați în Clinica de Gastroenterologie a Spitalului Clinic Județean de Urgență ”Sfântul Apostol Andrei” Galați.

MATERIAL ŞI METODĂ

Studiul prospectiv a inclus 122 bolnavi cu CH şi ascită internați în Clinica de Gastroenterologie a Spitalului Clinic Județean de Urgență ”Sfântul Apostol Andrei” Galați în perioada 1 ianuarie 2007-31 decembrie 2007 şi monitorizați pe o perioadă de 36 luni. Diagnosticul CH s-a stabilit pe baza criteriilor clinice, ecografice şi histologice. Severitatea cirozei hepatice s-a apreciat folosind scorurile Child-Pugh şi MELD (model for end-stage liver disease). Scorul MELD s-a calculat utilizând formula: 9,57 x log e (creatinina, mg/dl) + 3,78 x log e (bilirubina, mg/dl) + 11,2 x log e (INR) + 6,43.

Bolnavii au fost evaluați anamnestic, clinic, biologic (teste standard de laborator, incluzând hemoleucograma, teste biochimice hepatice şi renale, indice de protrombină, examen de urină) şi imagistic (ecografie abdominală, radiografie toracică). Paracenteza diagnostică şi cultura lichidului de ascită s-au efectuat la internarea pacienților şi în cazul apariției în cursul spitalizării a simptomelor şi semnelor sugestive pentru PBS (febră, dureri abdominale, alterarea statusului mintal, hipotensiune arterială, deteriorarea funcției renale, leucocitoză) în absența altor factori precipitanți identificabili. Lichidul de ascită s-a recoltat în recipiente sterile, respectând condițiile de asepsie. În fiecare recipient cu mediu de cultură MacConkey agar s-au inoculat cel puțin 10 ml de lichid de ascită, iar bacteriile identificate prin cultură au fost testate pentru sensibilitate la antibiotice prin metoda difuziunii.

Diagnosticul PBS s-a stabilit prin evidențierea în lichidul de ascită a peste 250 PMN /mm^3 în absența semnelor clinice şi radiologice de peritonită bacteriană secundară. Peritonita bacteriană secundară se

defineşte prin identificarea în lichidul de ascită a două sau mai multe microorganisme sau asocierea PMN > 250 /mm^3 lichid ascită cu cel puţin doi din următorii trei parametri: glucoza < 50mg/dl, proteine totale > 1g/dl şi lactat dehidrogenaza (LDH) peste limita superioară a normalului a LDH seric.

Bolnavii cu PBS au primit tratament empiric cu Ceftazidim (cefalosporină de generaţia a III-a) intravenos, 1-2g/12 ore, minimum 5 zile, întrucât aceasta a reprezentat opţiunea terapeutică disponibilă pe perioada spitalizării, studiile indicând o eficienţă similară cu a cefotaximului. Doza antibioticului a fost ajustată conform funcţiei renale pe perioada tratamentului. În cazurile cu eşec terapeutic la antibioticul iniţial, tratamentul a fost adaptat conform antibiogramei sau empiric.

Paracenteza diagnostică s-a repetat după 48 ore de la începerea antibioterapiei pentru stabilirea eficienţei acesteia. Lipsa de răspuns la tratament s-a considerat în cazurile ce au prezentat alterarea stării generale, scăderea PMN < 25% faţă de valoarea iniţială, menţinerea culturilor pozitive după 48 ore de antibioterapie sau care au decedat înaintea repetării paracentezei. Vindecarea PBS s-a apreciat în condiţiile remiterii tuturor semnelor clinice de infecţie, scăderii PMN în lichidul de ascită < 250/ mm^3, normalizării leucocitelor în sângele periferic şi negativării culturilor din lichidul de ascită. Bolnavii care au primit chinolone p.o. mai mult de o lună înaintea episodului de PBS au fost incluşi în grupul cu antibioticoprofilaxie. Mortalitatea intraspitalicească a fost definită ca deces de orice cauză în cursul spitalizării.

Datele au fost exprimate ca medie ± deviaţie standard (DS). Pentru compararea grupurilor s-au utilizat testele *t-Student* (pentru date cantitative) şi χ^2 (pentru date calitative). Prin analiză univariată au fost identificaţi factorii predictivi ai mortalităţii intraspitaliceşti. Variabilele analizate au fost vârsta, sexul, cauza cirozei, PBS, datele clinice şi de laborator efectuate (inclusiv scorurile Child-Pugh şi scorul MELD). Variabilele cu semnificaţie statistică ($p<0,05$) la analiza univariată au fost folosite la analiza multivariată, aplicându-se analiza regresivă logistică binară „stepwise" pentru identificarea factorilor predictivi ai supravieţuirii. În scopul determinării semnificaţiei datelor la analiza multivariată s-a utilizat intervalul de încredere (IC) de 95%, valoarea $p<0,05$ fiind considerată statistic semnificativă. Datele au fost prelucrate folosind *SPSS 17.0*.

REZULTATE

Studiul a inclus 34 episoade de PBS dezvoltate de 29 pacienţi (21 bărbaţi şi 8 femei) din cei 122 bolnavi cu CH şi ascită internaţi în clinică, stabilindu-se o prevalenţă a PBS de 23,77%. Caracteristicile demografice şi clinice ale cazurilor selectate la momentul diagnosticului PBS sunt prezentate în tabelul I. Vârsta medie a fost 56,89±8,79 ani, iar sexul masculin a fost predominant (72,41%). Consumul de alcool a reprezentat cauza cea mai frecventă a CH (68,96%), urmat de infecţia cu virus hepatitic C (34,48%) şi virus hepatitic B (27,58%). Din punct de vedere al clasificării Child-Pugh, a predominat clasa Child C (75,86%), urmată de Child B (24,14%); nici un bolnav nu s-a situat în clasa Child A. Scorul MELD mediu a fost de 21,8 ± 7,4. Majoritatea cazurilor cu PBS au fost simptomatice, febra şi durerile abdominale, fiind cel mai frecvent întâlnite în 18 cazuri (52,94%), respectiv 14 cazuri (41,17%). Encefalopatia hepatică la momen-

tul diagnosticului PBS a fost prezentă în 10 cazuri (29,41%) şi ca simptom unic al PBS în 3 cazuri (8,82%), iar insuficienţa renală în 13 (38,23%) din cazuri. Identificarea factorilor de risc pentru apariţia PBS a fost posibilă în 14 cazuri: 5 cazuri cu antecedente de PBS (4 dintre acestea având antibioticoprofilaxie pentru PBS la momentul internării), 6 cu hemoragie digestivă superioară şi 3 cu proceduri invazive (tab. I).

TABELUL I
Caracteristicile lotului studiat

Vârsta (ani)	56,89±8,79
Bărbaţi/Femei	21/8
Cauza cirozei, n (%)	
Consum de alcool	20 (68,96)
Virus hepatitic C	10 (34,48)
Virus hepatitic B	8 (27,58)
Clasa Child-Pugh (media ± DS)	11,68 ± 2,28
Scorul Child-Pugh, n (%)	
Clasa Child B	7 (24,14)
Clasa Child C	22 (75,86)
Scorul MELD	21,8 ± 7,4
Manifestări clinice, n (%)	
Febră	18 (52,94)
Dureri abdominale	14 (41,17)
Greaţă/vărsături	7 (20,58)
Encefalopatie hepatică	10 (29,41)
Hemoragie gastro-intestinală	6 (17,64)

Cultura pozitivă din lichidul de ascită s-a înregistrat în 12 (35,29%) din cele 34 de cazuri de PBS. Bacteriile Gram-negative (BGN) au reprezentat 66,67% din totalul germenilor identificaţi (8 din 12 cazuri). *Escherichia coli* a fost cel mai frecvent întâlnită (5 cazuri, 41,66%), urmată de *Klebsiella pneumoniae* (3 cazuri, 25%). Cocii Gram-pozitivi au fost prezenţi în 4 cazuri (33,33%) (2 *Streptococcus pneumoniae*, 1 *Staphylococcus aureus* şi 1 *Enterococcus faecalis*). Comparând grupurile de PBS determinate de bacterii Gram-pozitive şi Gram-negative s-a constatat că distribuţia pacienţilor nu a fost semnificativ diferită în ceea ce priveşte scorul Child-Pugh (p = 0,083) şi mortalitatea intraspitalicească (p = 0,246), însă scorul MELD, leucocitele, PMN şi proteinele din lichidul de ascită (LA) au fost semnificativ diferite între cele 2 grupuri (p = 0,042, 0,026, 0,029 şi, respectiv, 0,027). În acelaşi timp, scorurile Child-Pugh şi MELD au prezentat valori mai reduse în cazurile de PBS cu bacterii Gram-pozitive (BGP) (tab II).

Testarea sensibilităţii *in vitro* a bacteriilor a arătat că 5 bacili Gram-negativi (62,5%) au fost rezistenţi la Ampicilină şi 2 (25%) la Ciprofloxacin. Rezistenţa la Ceftazidim s-a înregistrat în 4 cazuri (2 *Escherichia coli*, 1 *Klebsiella pneumoniae* şi 1 *Enterococcus faecalis*), identificate ca fiind bacterii producătoare de beta-lactamază cu spectru extins (BLSE), sensibile, însă, la Imipenem şi Meropenem.

TABELUL II

Caracteristici clinice şi biologice ale pacienților şi bacteriilor izolate

	BGP (n=4)	**BGN (n=8)**	**Valoare p**

Creatinină	1,8±0,6	1,9±0,4	0,681
Bilirubină	7,6±3,1	6,0±0,9	0,255

Tratamentul empiric cu Ceftazidim s-a început în 26 cazuri (76,47%). În celelalte 8 cazuri, s-a folosit un alt antibiotic întrucât: 6 au dezvoltat PBS în pofida tratamentului cu cefalosporine inițiat în scop profilactic înaintea procedurilor invazive sau pentru HDS), iar 2 pacienți prezentau alergie la cefalosporine. Antibioticele de primă linie au fost administrate timp de 9±4 zile. Răspunsul la tratament s-a constatat în 19 cazuri tratate inițial cu Ceftazidim (73,07%), în timp ce în 5 cazuri (19,23%) a fost necesară schimbarea terapiei empirice datorită scăderii cu < 25% a PMN în lichidul de ascită la paracenteza efectuată după 48 ore de la începerea antibioterapiei. În aceste cazuri, tratamentul antibiotic a fost schimbat cu Imipenem în 4 cazuri şi Ciprofloxacin în 1 caz. În cele 5 cazuri cu eșec terapeutic la Ceftazidim bacteriile identificate au fost fie rezistente la Ceftazidim (4 producătoare de BLSE – 2 *Escherichia coli*, 1 *Klebsiella pneumoniae* şi 1 *Enterococcus faecalis*), fie au avut o sensibilitate redusă la Ceftazidim (*Staphylococcus aureus*). Dintre bolnavii care au primit ca tratament de primă intenție Ceftazidim, 2 au decedat înaintea începerii antibioterapiei de linia a doua, iar doi în decurs de 72 ore după schimbarea tratamentului antibiotic.

Eşecul la tratamentul empiric s-a produs în 9 cazuri (26,47%): 7 cazuri tratate cu Ceftazidim, 1 caz tratat cu Ciprofloxacin şi 1 caz tratat cu Amoxicilină-acid clavulanic. Analiza multivariată a identificat scorul MELD la internare (p = 0,027) şi PBS produse de bacterii producătoare de BLSE (p = 0,004) ca factori predictivi independenți pentru eşecul tratamentului antibiotic empiric. Remiterea PBS s-a obținut în 22 din 26 cazuri tratate inițial cu Ceftazidim (84,61%), 4 bolnavi decedând. Decesul a survenit în 2 din cele 8 cazuri care au primit ca tratament de primă linie un antibiotic diferit de Ceftazidim. Mortalitatea intraspitalicească a fost de 17,64%. Cauzele deceselor au fost reprezentate de: hemoragie digestivă superioară (3 cazuri), sindrom

hepato-renal (2 cazuri) şi encefalopatie hepatică (comă) 1 caz. Pe parcursul perioadei de monitorizare recurenţa PBS s-a produs în 5 cazuri (21,73%) din cei 23 bolnavi ce au supravieţuit primului episod de PBS şi care au beneficiat de profilaxie secundară antibiotică cu chinolone.

La analiza multivariată variabile independente în relaţie cu mortalitatea în PBS au fost insuficienţa renală (creşterea azotului ureic şi/sau creatininei serice peste 30 mg/dl, respectiv, 1,5 mg/dl) (p= 0,038), scorul MELD la internare (p = 0,017) şi PBS cu bacterii producătoare de BLSE (p = 0,026).

DISCUŢII

Scopul studiului prospectiv a fost de a evalua trăsăturile clinice actuale, răspunsul terapeutic şi prognosticul cirozelor hepatice complicate cu PBS internate în Clinica de Gastroenterologie din Spitalul Judeţean Galaţi. Aceasta analiză este justificată de modificările din ultimii ani referitoare la tipul şi etiologia infecţiilor bacteriene în ciroza hepatică (7, 8, 9). Pentru aceasta, studiul a evaluat un grup de pacienţi cu ciroză hepatică cu ascită complicată cu PBS, care au fost monitorizaţi timp de 36 luni.

Rezultatele studiului susţin recomandările ghidurilor actuale privind stabilirea diagnosticul PBS prin numărarea PMN în lichidul de ascită şi iniţierea tratamentul empiric cu cefalosporine de generaţia a III-a (în studiul prezentat Ceftazidim), avându-se în vedere necesitatea schimbării antibioticului doar în 19,23% din cazuri. Ca urmare, Ceftazidimul poate fi considerat ca opţiune terapeutică în PBS, prezentând o eficienţă similară cu a cefotaximului - antibioticul recomandat de ghidurile actuale ca tratament de primă intenţie a PBS.

Cazurile cu eşec terapeutic la Ceftazidim datorat fie bacteriilor producătoare de BLSE (*Escherichia coli*, *Klebsiella pneumoniae*, *Enterococcus faecalis*), fie sensibilităţii bacteriene reduse la Ceftazidim (*Staphylococcus aureus*) au avut un prognosticul rezervat, cu o rată crescută de mortalitate (50%). Aceste date indică prezenţa bacteriilor producătoare de BLSE ca fiind un factor predictiv independent pentru eşecul terapeutic şi mortalitatea intraspitalicească. Bacteriile producătoare de BLSE au fost rezistente la toate antibioticele, cu excepţia Imipenem şi Meropenem. Ca urmare, în condiţiile identificării prin cultură a bacteriilor producătoare de BLSE sau al eşecului terapeutic la administrarea de cefalosporine de generaţia a III-a, ar trebui avută în vedere înlocuirea antibioticului iniţial cu Imipenem sau Meropenem.

Diagnosticul precoce al PBS, iniţierea tratamentului antibiotic empiric şi adaptarea ulterioară a acestuia conform rezultatelor antibiogramei a permis controlul eficient al infecţiei şi reducerea mortalităţii intraspitaliceşti la 17,64%, rezultatele fiind în concordanţă cu datele din literatura de specialitate (10).

În acest studiu, prezenţa la internare a disfuncţiei renale şi scorul MELD au fost identificaţi ca factori predictivi independenţi ai mortalităţii în PBS, rezultate similare fiind raportate de alte studii (11, 12). Pe de altă parte, aceşti factori se corelează, de obicei, cu prezenţa unei insuficienţe hepatice avansate.

Datele din literatură indică o incidenţă în creştere a bacteriilor Gram-pozitive implicate în etiologia PBS de la 25% în anii 1998-1999 şi la 59% între 2000-2002 (13). În studiul prezentat proporţia cazurilor de PBS cu bacterii Gram-pozitive a fost doar 33,33%. În grupul studiat cazurile de

PBS cu bacterii Gram-pozitive au prezentat valori mai reduse ale scorurilor Child-Pugh şi MELD şi concentraţii superioare ale proteinelor în lichidul de ascită, comparativ cu PBS cu bacterii Gram-negative.

Ghidurile terapeutice actuale recomandă profilaxia pe termen lung prin administrarea zilnică de Norfloxacin la pacienţii care au prezentat un episod de PBS. Însă, profilaxia cu Norfloxacin ar putea contribui la creşterea frecvenţei PBS cu bacterii rezistente la chinolone, existând studii care au raportat dezvoltarea de bacili Gram-negativi rezistenţi la chinolone în flora intestinală a bolnavilor cirotici ce au primit profilaxie pe termen lung cu Norfloxacin (14).

CONCLUZII

Peritonita bacteriană spontană este o complicaţie frecventă şi severă, ce survine în cazurile de ciroză hepatică cu ascită internate în spital.

Paracenteza diagnostică trebuie efectuată în toate cazurile de ciroză hepatică cu ascită şi când apar manifestări clinice sugestive precum durerile abdominale, febra, encefalopatia hepatică, agravarea disfuncţiei renale sau hepatice. În prezenţa a peste 250 PMN /mm^3 în lichidul de ascită se stabileşte diagnosticul PBS (cultura bacteriană pozitivă nu este absolut necesară) şi se iniţiază tratament antibiotic empiric, preferabil cu cefalosporine de generaţia a III-a (Ceftazidim în studiul prezent). În cazurile cu eşec terapeutic la Ceftazidim trebuie avută în vedere schimbarea acestuia cu Imipenem sau Meropenem.

În pofida progreselor diagnostice şi terapeutice recente, PBS încă se asociază cu o mortalitate semnificativă la bolnavii cu ciroză hepatică, în special în cazurile cu scor MELD ridicat.

MODULAREA EXPRESIEI GENELOR DE VIRULENTA ALE *STAPHYLOCOCCUS AUREUS* DE CATRE ANTIBIOTICE BETA-LACTAMICE UTILIZATE IN CONCENTRATII SUBINHIBITORII

Stimularea expresiei genelor de virulență de către concentrații subinhibitorii ale anumitor antibiotice poate modifica evoluția infecției și poate face ca terapia antimicrobiană să devină ineficientă. Investigarea efectelor concentrațiilor subinhibitorii ale antibioticelor care inhibă sinteza peretelui bacterian asupra expresiei genelor de virulență și asupra producerii biofilmului la *Staphylococcus aureus* a fost realizată folosind metode difuzimetrice și prin real time PCR cantitativ. Expresia genelor *spa* (*staphylococcal protein* A) și *luk*E a fost stimulată de concentrații subinhibitorii de penicilină și cefalotin, în timp ce expresia *agr* RNAIII (*accessory gene regulator*) nu a fost afectată. De asemenea, s-a observat producerea unui biofilm mai dens în prezența unor concentrații subinhibitorii de cefalotin (Subrt N, Mesak LR, Davies J. Modulation of virulence gene expression by cell wall active antibiotics in *Staphylococcus aureus. J Antimicrob Chemother*. 2011; 66: 979-84).

THE THERAPEUTIC APPROACH TO DEEP VENOUS THROMBOSIS IN THE PATIENT WITH CIRRHOSIS OF THE LIVER (Abstract): Venous thromboembolism is considered a very rare event in patients with liver cirrhosis, thus explaining unpredictable outcome. This may be due to the severe liver disease profoundly affecting coagulation. Patients with cirrhosis also have a reduction in anticoagulant proteins so their coagulative situation is characterized by a new balance of pro- and anticoagulation factors, defined as "rebalanced hemostasis". Starting from the existing data in the literature so far, we studied 8 male patients previously known with cirrhosis, who were hospitalized with deep vein thrombosis (DVT) in the lower limbs in the Cardiology Clinic. The therapeutic approach to deep venous thrombosis associated with liver cirrhosis raises some issues related to the particular bleeding risk in this category of patients. DVT is not a rare condition in cirrhosis. The diagnosis of liver cirrhosis had been previously confirmed and justified by the presence of medical records at admission, and the diagnosis of DVT was based on clinical symptoms of DVT and confirmed using Duplex Doppler ultrasonography criteria for DVT. Viral etiology of cirrhosis was predominant and diabetes mellitus was the only variable that was significantly associated with the presence of DVT. It is important though to consider, that serum albumin level of less than 3 mg/dL tended to be a risk factor. Our results coincide with those reported in the studied literature. The treatment unanimously accepted so far, initially with low-molecular-weight heparin (for 7-10 days) continued with Acenocumarol is adequate, with a low risk of bleeding. The precise mechanisms of hypercoagulability and thrombosis in cirrhosis are not well known and need further investigation. **Keywords:** DEEP VEIN THROMBOSIS, CIRRHOSIS, ANTICOAGULANT.

Currently, it is widely accepted that the liver plays an essential role in the coagulation cascade, which is why the global hemostatic process is deeply influenced by the presence of hepatic disease and its complications (1, 2). Patients with liver cirrhosis, especially those at an advanced stage of disease, have a low synthesis of most factors involved in coagulation and fibrinolysis. This is due to reduced hepatic function and secondary thrombocytopenia of portal hypertension. Severe liver disease profoundly affects coagulation. Impairment of coagulation tests and thrombocytopenia

have previously been associated with an increased risk of bleeding, which is why these patients were "auto-anticoagulated" and therefore "protected" against thrombotic events. This paradigm has been abolished because outside of gastrointestinal bleeding, spontaneous bleeding is not very frequent in cirrhotic. The latest clinical findings support the idea that the cirrhotic patient is exposed to both thrombotic and hemorrhagic events (1, 2).

The therapeutic approach to deep venous thrombosis associated with liver cirrhosis raises some issues related to the particular bleeding risk in this category of patients. The decreased hepatic synthetic function and the hemodynamic alterations due to portal hypertension exert a profound influence on the hemostatic balance. This accounts for the presence of altered coagulative parameters in patients with chronic liver disease. Routine blood tests (like International Normalized Ratio [INR] or Partial Thromboplastin Time [PTT] do not accurately evaluate the coagulative performance in these patients. Thromboelastography is recommended as the most faithful method of assessing coagulation status in the cirrhotic patients (2).

Deep vein thrombosis (DVT) is a serious disorder that often complicates the course of hospitalized patients. Rudolf Virchow was the first who proposed that thrombosis was the result of three underlying pathogenic factors (stasis of blood flow, hypercoagulability and vascular endothelial damage) (1). Many risk factors have been linked to the occurrence of venous thromboembolism (VTE) including age, cancer, acute respiratory failure, congestive heart failure, acute infection, dehydration, rheumatologic disease, etc. (3, 4).

Lesmana *et al*. (1) reported a prevalence of DVT in patients with liver cirrhosis at 4.7%. They considered deep vein thrombosis being a non-rare condition in cirrhotic patients with coagulopathy that warrants further studies on the mechanisms and prevention.

Several studies indicate the incidence of non-portal VTE in patients with chronic liver disease in the range between 0.5% and 6.3% (1, 5-9). Two retrospective studies by Northup *et al*. (8) and Garcia-Fuster *et al*. (9), showed that the risk of developing VTE increases in patients with low serum albumin, but is independent from elevated INR or low platelet count. Serum albumin is a marker of liver synthetic function, and hence, indirectly, of the imbalance of serum levels of anticoagulant factors as antithrombin III, protein C and protein S. This explains the increased risk of VTE in these patients.

A retrospective study by Dabbagh *et al*. (10) confirmed that an elevated INR (even >2.2) does not protect patients with chronic liver disease against the risk of VTE. Other studies showed that not only patients with cirrhosis are not naturally auto-anticoagulated, but that they also seem to have an increased relative risk of venous thromboembolism (both deep vein thrombosis and pulmonary embolism) compared with the control patients (9-12).

Wu *et al*. (13) assessed the incidence of VTE in patients with compensated or decompensated cirrhosis and a random sample of control patients. Interestingly, results indicated that patients younger than 45 years had an increased risk of VTE, either if they were being compensated or decompensated. After 45 years of age, patients with compensated cirrhosis had a lower risk of VTE, while those with decompensated disease had a similar risk compared

with controls. These results may be explained with age-related factors not correlated with liver disease; in younger patients, who normally have low baseline risk of VTE, presence of cirrhosis implies an increased risk of VTE compared with non-cirrhotic patients, whereas in older patients' extrahepatic factors seem to outweigh liver-related risk factors.

Starting from the existing data in the literature so far, we studied during the 2014-2018 period, 8 male patients previously known with cirrhosis were hospitalized with deep vein thrombosis (DVT) in the lower limbs in the Cardiology Clinic. The diagnosis of liver cirrhosis had been previously confirmed and justified by the presence of medical records at admission, and the diagnosis of DVT was based on clinical symptoms of DVT (unilateral swollen or painful leg) and confirmed using Duplex Doppler ultrasonography criteria for DVT. They are the following: no flow signal, direct clot visualization, the absence of spontaneous flow, and the absence of respiration-modulated phasicity of the evaluated veins. Valvular competence was assessed using the Valsalva maneuver.

Patients were aged between 33-63 years and all of them were males. Five of them developed DVT during hospitalization for cirrhosis, which was confirmed clinically by the observation of swollen calf with rash and tenderness, together with Duplex Doppler ultrasonography. Three of the patients were admitted in the Emergency Department. Regarding the location of DVT in 5 cases it was at the level of the popliteal vein (right in 3 cases and left in 1 case), and in 3 cases it was a high DVT of the left ilio-femoral vein. There was no relation between the localization of thrombosis and the biochemical profile in our patients. The platelet count was between 95.000 and 125.000/ mm^3 and no active bleedings were present at the admission.

All patients were treated initially with low-molecular-weight heparin (for 7-10 days) and then with Acenocumarol to maintain INR between 2 and 3. Three of the patients showed ascites on admission and no patient with hepatic encephalopathy was found. One patient was previously diagnosed with diabetes mellitus and he was under insulin therapy. Also, no significant variations in platelet counts and no bleedings occurred during anticoagulation therapy.

Other risk factors, such as smoking, obesity, dyslipidemia, or status of inherited hypercoagulability, were not known. Viral etiology was predominant in the group of cirrhotic patients with DVT (6 patients out of 8), but with no statistical significance. Diabetes mellitus was the only variable that was significantly associated with the presence of DVT. Subsequent multivariate analysis confirmed diabetes mellitus as an independent risk factor for developing DVT in patients with liver cirrhosis with a high odds ratio. However, serum albumin level of less than 3 mg/dL tended to be a risk factor. These results coincide with those reported in the studied literature.

Venous thromboembolism is considered a very rare event in patients with liver cirrhosis, with unpredictable course and unclear mechanism. Viral hepatitis was the predominant cause of cirrhosis in our study (5 cases out of 6) compared with alcoholic and nonalcoholic steatohepatitis in Northup's study (8). Diabetes mellitus was present only in one case and, as we know, it is a risk factor for the occurrence of DVT.

We did not find any association between the clinical factors, such as sex, age,

and laboratory findings, and the presence of DVT in liver cirrhotic patients. Because of the small number of patients, no laboratory marker could be used as a predictor for prothrombotic state, including serum albumin levels. Most of our patients came already with low serum albumin levels (less than the normal cutoff point of 3.0 mg/dL). This data explains why serum albumin levels failed to show significant association with the presence of DVT. Low albumin level may indicate an advanced liver disease in most of our study subjects. In addition, it may be used as an indirect marker for the decreased synthesis of other proteins produced by the liver (7–10). There are other factors, such as protein C, protein S, and antithrombin III, that are involved as natural anticoagulants. During acute or chronic liver disease, their concentrations decrease concomitantly with other coagulation factors, but usually are not lower than 20% of the normal values. Decreased natural anticoagulants, therefore, could be another risk factor for developing DVT.

We identified diabetes mellitus as an independent risk factor for developing DVT. This observation was not surprising, since the risk of VTE is increased in diabetic patients (12). Other features of endocrinological disturbances, such as obesity and dyslipidemia, might be risk factors of DVT; however, a recent study concluded that symptoms of metabolic syndrome were not clinically important risk factors for VTE (14). Further studies are needed to confirm whether metabolic abnormalities, especially those with hepatitis C infection, could be the risk factors of DVT in patients with liver cirrhosis.

There are many risk factors and conditions predisposing to VTE such as age above 40 years, cancer with or without ongoing chemotherapy treatment, history of VTE, prolonged bed immobilization, surgery, trauma, obesity, smoking, and inherited hypercoagulable states (e.g., antithrombin deficiency, protein C and/or protein S deficiency, factor V Leiden, prothrombin gene mutation) (14). Besides, decreased synthesis of the natural anticoagulants, hypercoagulation in liver disease, could also be related to poor flow and vasculopathy associated with a chronic inflammatory state. The potential disease state favoring DVT or PE in patients with liver cirrhosis could be an imbalance in the clotting cascade favoring coagulation, immobilization associated with of end-stage liver disease, infection, and systemic inflammation (11, 12, 13). Our study showed that the age of the patients was between 33-63 years and most of them had chronic hepatic viral infection. Patients with this profile often need hospitalization due to the cirrhosis complications especially ascites. No patient of the group had encephalopathy. Immobilization during hospital stay is known as a risk factor for venous thrombosis due to the stasis of blood flow in the venous system. Therefore, patients with cirrhosis may share the same risk factors of VTE as other hospitalized patients. We did analyze the patients' length of stay before the occurrence of DVT symptoms and we concluded that the risk increased when the length of hospital stay was more than 6 days. No patient of the studied group presented electrocardiographic signs of pulmonary embolism or other arrhythmias (14, 15). As we mentioned, no active bleedings were present at admission, no bleeding during anticoagulation therapy and no significant variations in platelet counts as we would have expected (16). Cancer alone is a known risk factor of thrombosis. We also

analyzed the presence of hepatocellular carcinoma (HCC) and its association with DVT, but the presence of HCC apparently was not a risk factor for developing DVT in our study subjects because HCC was not discovered.

Only one of the patients (40 years old) died 2 months following the diagnosis, due to a respiratory infectious episode. Initial evolution under anticoagulation treatment appeared to be good and no hemorrhagic events were described.

Our study did have several limitations. Firstly, it was not designed prospectively, and it had a small number of patients. Also, DVT was suspected if the patient presented with clinical symptoms/signs suggestive of DVT and further confirmed by Doppler ultrasonography. We did not screen the patients' blood coagulation profile and, consequently, we might have overlooked patients with subclinical DVT.

The principal limitation of the study is related to the small number of patients which did not allow a statistical interpretation.

In our study we cannot estimate the real prevalence of DVT in our group of cirrhotic patients because of the small number of patients included, but, also taking other studies into account, we can appreciate that DVT is not a rare condition in cirrhosis. Diabetes mellitus was the only independent risk factor for developing DVT found in this study.

The treatment unanimously accepted so far, initially with low-molecular-weight heparin (for 7-10 days) continued with Acenocumarol is adequate, with a low risk of bleeding.

The precise mechanisms of hypercoagulability and thrombosis in cirrhosis are not well known and need further investigation.

SERUM CHOLINESTERASE: THE POWER OF PREDICTION

The role of cholinesterase to assess the liver reserves in hepatitis D patients has not been well defined. Therefore, the aim of this study was to determine the capacity of cholinesterase to predict liver function compared to actual synthetic liver function tests and scoring models in patients with hepatitis D and cirrhosis. In this observational, cross-sectional study were included 233 patients with cirrhosis due to chronic hepatitis D. Serum cholinesterase levels were correlated with existing scoring models for chronic liver disease and liver function tests like ascites, Child Turcotte Pugh (CTP), model for end stage liver disease (MELD) score, baseline-event-anticipation (BEA) score for hepatitis D and aspartate transaminase to Platelet Ratio Index (APRI). The results of this study showed well correlation of serum cholinesterase levels with serum albumin, INR and CTP, MELD, BEA and APRI scores and can be considered a prognostic marker of liver reserves in hepatitis D cirrhosis. Thereby, cholinesterase levels should be routinely checked to asses liver function and may be incorporated in MELD scoring. Also, it can be used to follow the staging of liver disease in hepatitis D (Minaam A, Zaigham A. Serum cholinesterase: a predictive biomarker of hepatic reserves in chronic hepatitis D. *World J Hepatol* 2017; 9(22): 953-978).

EPIDEMIOLOGY AND HISTOLOGY OF MALIGNANT THYROID NODULES IN NORTH EAST REGION OF ROMANIA (MOLDAVIA) BEFORE AND AFTER ALIMENTARY SALT UNIVERSAL IODINATION (Abstract): Research on the relationship between iodine exposure and thyroid cancer risk is limited and the findings are inconclusive. **Objectives**: Given this molecular data on iodine we decided to evaluate the changes of incidence and histology of thyroid cancer in the North-Eastern region of Romania (Moldavia) after the government decision from 2004 that introduced the universal iodination of alimentary salt. After this decision values of urinary iodine increased from 50 μg/L (2001–2002) to 117 μg/L (2006 -2008). **Material and methods** : We compared the incidence and the histology of thyroid cancer in residents living in an area known as a mild endemic goiter region (Moldavia-Romania) between 2001-2004 with the incidence and the histology of thyroid cancer between 2005-2008 in the same region after the introduction of universal iodization of alimentary salt. **Results:** The number of papillary cancers increased from 125 cases (2001-2004) to 276 cases (2005-2008). The number of follicular cancer decreased from 52 cases (2001-2004) to 27 cases (2005-2008). The ratio between papillary and follicular cancers increased from 4.80 / 1 (2001-2004) at 10.61 / 1 (2005-2008). The number of medullar thyroid carcinoma increased from six cases (2001-2004) to 24 cases (2005-2008). Thyroid anaplastic carcinomas number increased from 7 cases (2001-2004) to 12 cases (2005-2008). The total number of thyroid cancer has increased dramatically after the introduction of universal iodination of alimentary salt with 178% compared to 2001-2004 (from 190 cases in 2001-2004 to 339 cases in 2005-2008), despite the fact that the number thyroidectomies decreased from 1734 (2001-2004) to 1449 (2005-2008). **Conclusion**: After the introduction the universal iodination of alimentary salt starting from 2004 the total number of thyroid cancers increased comparative with the period before universal iodination of alimentary salt. **Key words:** ROMANIA, IODINE SALT PROPHYLAXIS, THYROID CANCER

Before the introduction of salt iodination in 2004 the North-Eastern Region of Romania was known to be a moderate iodine deficiency area. There are some studies documenting the spectrum of TC in iodine-deficient communities (1,2,3,4). Research on the relationship between iodine exposure and thyroid cancer risk is limited and the findings are inconclusive. The molecular mechanism for this relationship of iodine with PTC is unclear. Molecular studies in recent years have identified a T1799A transversion BRAF mutation that occurs in about 45% of PTC and 25% of apparently

PTC-derived anaplastic thyroid cancer but not in any other type of thyroid tumors, such as FTC and benign thyroid tumors. This mutation causes a valine-toglutamic amino acid change in codon 600 of the BRAF protein, resulting in constitutive activation of the BRAF kinase and the Ras 3 Raf 3 MAPK kinase 3 MAPK/ERK pathway. (5) Commencing iodine prophylaxis it has been noted a rise in incidence of PTC relative to the other tumor types but the role of iodine nutrition in the pathogenesis of TC is both complex and controversial (1,3, 6,7,8). Increased exposure to ionizing radiation, changes in iodine nutrition and greater recognition of thyroid neoplasia have all been postulated as contributory (3). The aim of current study was to examine the changes of incidence and histology of thyroid cancer after the government decision from 2004 that introduced the universal iodination of alimentary salt. As a consequence the values of urinary iodine increased from 50 μg/L (2001 – 2002) to 117 μg/L 2006 -2008 (9).

MATERIAL AND METHOD

We reviewed the records of 601 patients diagnosed with thyroid cancer in the Saint Spiridon Hospital Iasi between 2001 and 2008. We excluded cases with clinical features highly suggestive of thyroid cancer, but without histological diagnosis, consequent to refuse of thyroid FNAB or thyroidectomy

In our retrospective study we analyzed the data of patients diagnosed with thyroid cancer in Endocrinology Clinic of Iaşi between 2001 and 2008 and the data obtained from the histological registry of Institute of Pathology Iaşi regarding the same diagnosis in the mentioned period. This Institute examines the excised samples of all operations made in Iasi County. The Endocrinology Clinic and the Institute of Pathology Iaţi have the major role in the management of thyroid cancer cases arisen in Iasi County and in border counties. First of all, as the Endocrinology Clinic is the single institution of this specialty in Iaşi County, it deals with both adult and pediatric endocrine pathology. Secondly, in our county thyroid cancer cases are managed mainly by endocrinologists not by oncologists. Those patients who undergo thyroidectomy without previous endocrine exam, approach the endocrinologist after the intervention, and if not, the cases are registered by the histological exam provided by the Institute of Pathology Iaşi. We compared the incidence and the histology of thyroid cancer in residents living in an area known as a mild endemic goiter region (Moldavia-Romania) between 2001 and 2004 with the incidence and the histology of thyroid cancer between 2005 and 2008, in the same region after the introduction of universal iodization of alimentary salt.

RESULTS

During 2001-2008 a total number of 529 patients from Moldavia were diagnosed histological with thyroid cancer. A trend of impressive increase of incidence of differentiated thyroid cancers especially of papillary cancers but also anaplastic thyroid cancers was noticed between 2005-2008 comparative to 2001-2004. The number of papillary cancers increased from 125 cases (2001-2004) to 276 cases (2005-2008). The number of follicular cancer decreased from 52 cases (2001-2004) to 27 cases (2005-2008). The ratio between papillary and follicular cancers increased from 4.80 / 1 (2001-2004) at 10.61 / 1 (2005-2008). The number of medullar thyroid carcinoma increased from 6 cases (2001-2004) to 24 cases (2005-2008). Thyroid anaplastic thyroid carcinomas number increased from 7 cases (2001-2004) to 12 cases (2005-2008).

The total number of thyroid cancer has increased dramatically after the introduction of universal iodination of alimentary salt

with 178% compared to 2001-2004 (from 190 cases in 2001-2004 to 339 cases in 2005-2008), despite the fact that the number thyroidectomies decreased from 1734 (2001--2004) to 1449 (2005-2008).

DISCUSSION

There was a significant rise in the incidence of papillary, medulary and anaplastic thyroid cancers during the study period despite the fact that the number thyroidectomies decreased . The changes in pathological classification are unlikely to account for the observed changes in TC incidence and spectrum (2,10). Some studies explain as contributory to the rise in TC incidence the increased use of ultrasonography and fine needle biopsy (4,11) but this is unlikely to account for the observed increase in total number of thyroid cancers from our study because the diagnostic methods remained the same reported to the study made in 2001--2004 in the Endocrinology Clinic from Saint Spiridon Hospital Iasi. The role of iodine nutrition in the pathogenesis of TC is controversial (12). Case control studies have also produced contradictory findings, iodine--rich diets having been associated with both a heightened and an attenuated risk of TC (10,13). Despite the conflicting results, a consistent association has been the link between iodine nutrition and tumor histology (11,14). The incidence of FTC is greatest in iodine-deficient populations, whereas the converse is true in regions of iodine sufficiency (1,7,10). Consistent with this observation, iodine prophylaxis is associated with a rise in the proportion of differentiated TC ; so called "papillarization" of TC (15). This is evidenced by a rise in the proportion PTC relative to FTC (3,6). However this does not explain the increasing number of medullar and anaplastic thyroid cancers during 2005--2008 comparative with the period before universal iodination of alimentary salt.

A complex interaction between iodine nutrition and thyroid tumorigenesis may account for our findings.

CONCLUSIONS

There was a significant rise in the incidence of total TC during the study period especially due to an increasing incidence of PTC. Additional studies are required to clarify the relationship between iodine nutrition and thyroid tumorigenesis. In particular, longitudinal data spanning transition from iodine sufficiency to deficiency should establish the contributions of improved diagnostic practice, environmental carcinogens and iodine nutrition to the observed changes in the spectrum of TC.

Universitatea de Medicină şi Farmacie "Gr.T. Popa" Iaşi
Facultatea de Medicină
Institutul de Gastroenterologie şi Hepatologie Iaşi

COLONOSCOPIC SCREENING OF ASYMPTOMATIC INDIVIDUALS WITH A FAMILY HISTORY OF COLORECTAL CANCER (Abstract): Background and Aims: First--degree relatives of colorectal cancer (CRC) patiens are at increased risk for developing colorectal neoplasm. The aim of our study was to evaluate the use of total colonoscopy as the screening test in asymptomatic individuals with a family history of colorectal cancer. **Material and method**: Colonoscopy was performed in 125 asymptomatic individuals (64 men and 61 women; mean age 51.7 ± 11.5 years, range 24-77 years) who had one or two first-deegree relatives with CRC. **Results**: Forty-five colorectal lesions were found in 36 subjects (28.8%): one (0.8%) adenocarcinoma, and 44 polyps (31 adenomas; 13 hiperplasic) (28.0%). The cecum was intubated in 96% of cases, and the procedure was generally well tolerated without complications. **Conclusions**: Total colonoscopy is a useful and safe screening procedure for the examinations of asymptomatic individuals with a family history of CRC. **Key words**: COLONOSCOPY, SCREENING, FAMILIAL COLON CANCER, FIRST-DEGREE RELATIVES

Cu peste un milion de cazuri noi şi aproximativ 500.000 de decese anual, cancerul colorectal (CCR) este o problemă majoră de sănătate publică la nivel mondial (1).

În România, asistăm la o creştere îngrijorătoare a prevalenţei CCR, care aproape s-a dublat în decursul unui deceniu (15,28%000 locuitori în 1996, ajungând la 28,6%000 locuitori în 2006) (2).

Aproximativ 20% din totalitatea cancerelor colorectale este reprezentat de CCR familial, care apare la pacienţi cu aglutinări familiale, dar nu respectă un model de transmitere ereditară (3,4). Riscul familial de CCR în prezenţa unei rude de gradul I este de 2-3 ori mai mare decât în populaţia generală şi creşte de 3-4 ori în prezenţa a două rude de gradul I cu CCR sau a unei rude de gradul I diagnosticată până la vârsta de 50 ani (5,6).

Scopul screening-ului este de a reduce mortalitatea prin reducerea incidenţei cazurilor avansate de boală. Screening-ul CCR poate atinge acest obiectiv prin detectarea adenocarcinoamelor într-un stadiu precoce, detectarea şi excizia polipilor adenomatoşi prin polipectomie endoscopică (7,8).

Colonoscopia este considerată cea mai bună metodă de screening pentru CCR pe care ghidurile actuale o recomandă la persoanele cu istoric familial de CCR (9-11).

Scopul studiului nostru a fost evaluarea oportunităţii unui program de screening pentru CCR la rudele de grad I a pacienţilor cu această boală malignă utilizând colonoscopia.

MATERIAL ŞI METODĂ

Studiul s-a desfăşurat în Institutul de Gastroenterologie şi Hepatologie (IGH) Iaşi, în perioada mai 2008 – iunie 2010, iar participanţii la acest studiu au fost rudele de

grad I a 460 pacienţi diagnosticaţi cu cancer colorectal. Din ianuarie 2008 am procedat la informarea detaliată a pacienţilor cu CCR privind incidenţa crescută a acestei boli maligne la rudele cu istoric familial şi importanţa diagnosticării acestui tip de cancer într-un stadiu precoce, vindecabil. Pacienţii au fost rugaţi să informeze rudele despre riscul crescut al bolii şi să le invite să participe la acest studiu. De asemenea, au fost trimise invitaţii la rudele pacienţilor, care cuprindeau un scurt material informativ despre riscul crescut în apariţia CCR la persoanele cu istoric familial de CCR şi posibilitatea depistării bolii într-un stadiu iniţial, vindecabil. Persoanele care au răspuns invitaţiei au primit informaţii suplimentare despre importanţa diagnosticului precoce a CCR cu ajutorul colonoscopiei, cu explicaţii detailate asupra procedurii endoscopice şi avantajelor metodei (posibilitatea examinării întregului colon, prelevarea de biopsii şi excizia polipilor depistaţi), fiind de asemenea atenţionaţi asupra discomfortului în timpul examinării şi potenţialele riscuri. După pregătirea corespunzătoare cu preparate orale de tip polietilen glicol (Fortrans) şi obţinerea consimţământului, participanţii au fost investigaţi colonoscopic la IGH Iasi. În studiu au fost incluse persoane fără semne sugestive pentru CCR şi fără comorbidităţi severe care să interfereze cu realizarea colonoscopiei. Costurile au fost suportate de instituţia medicală, iar colonoscopia a fost efectuată de medici gastroenterologi experimentaţi, competenţi în endoscopie digestivă.

Pentru identificarea tipului histologic polipii depistaţi au fost biopsiaţi. Persoanelor cu un rezultat negativ la colonoscopie li s-a recomandat supraveghere colonoscopică la 5 ani.

REZULTATE

Dintre cele 460 persoane invitate, 245 (53,3%) au răspuns invitaţiei şi s-au arătat interesate de studiu, iar 125 (27,1%) s-au prezentat în perioada mai 2008-iunie 2010 la IGH pentru efectuarea colonoscopiei. Participarea la studiu a evidenţiat preponderenţa

TABELUL II
Rezultatele examenului colonoscopic

Rezultat colonoscopie	Nr. pacienți	%	Observații
Colonoscopie normală	48	38,4	
Adenocarcinom	1	0,8	Localizare: rectală Stadiu: Dukes B (T3N0)
Polipi	35	28	Nr. polipi: 44 Localizarea: rect-1; colon stâng-28; colon drept-15 ; Diametru: <10 mm-31 polipi; peste 10 mm-13 polipi Polipectomie: 24 pacienți
Boală hemoroidală	31	24,8	
Diverticuloză	10	8	

TABELUL III
Examinarea histologică a leziunilor depistate

Leziune	Număr = 45	%
Adenocarcinom	1	2,2
Adenoame tubulare	18	40,0
Adenoame tubulo-viloase	8	17,8
Adenoame viloase	5	11,1
Polipi hiperplazici	13	28,9

nesemnificativă a sexului masculin - 64 bărbaţi (51,2%) faţă de 61 femei (48,8%), si a inclus persoane cu vârsta cuprinsă între 24 şi 77 ani (vârsta medie: 51,7 ± 11,5 ani), majoritatea provenind din mediul urban. Caracteristicile demografice ale lotului de studiu sunt prezentate în tabelul I.

În total, au fost identificate 45 leziuni la 36 pacienţi (28,8%): un adenocarcinom (0,8%) şi 44 de polipi (28%) (tab. II). Examinarea histologică a polipilor a confirmat 31 polipi adenomatoşi (18 polipi tubulari, 8 polipi tubulo-viloşi, 5 polipi viloşi) şi 13 polipi hiperplazici. La 14 pacienţi (11,2%) polipii depistaţi reprezentau adenoame avansate (definite cele cu diametrul = 10 mm sau histologic cu displazie de grad înalt sau cu componentă viloasă) (tab. III).

Examinarea completă a colonului s-a reuşit la 120 pacienţi (96%). Procedura a fost bine tolerată, fără complicaţii, sedarea conştientă fiind folosită în rare cazuri.

DISCUŢII

Creşterea incidenţei şi prevalenţei CCR la nivel mondial a trezit un interes sporit în lumea medicală pentru implementarea programelor de screening. CCR îndeplineşte pe deplin criteriile stabilite de OMS pentru instituirea unor astfel de programe: boală cu incidenţă şi mortalitate semnificative, asimptomatică pentru o perioadă îndelungată, dezvoltată din leziuni premaligne, progresie lentă (ani) din stadiile precoce, curabile, la cele avansate, teste de screening accesibile, fără riscuri şi eficiente în reducerea morbidităţii şi mortalităţii (12).

Reducerea incidenţei şi mortalităţii prin CCR în ţările unde s-au aplicat programe de screening a fost atribuită depistării bolii într-un stadiu incipient şi îndepărtarea polipilor adenomatoşi prin polipectomie endoscopică (13-16).

Colonoscopia este considerată de mulţi autori ca „gold standard" în screening-ul CCR, depăşind ca eficacitate FOBT (*fecal occult blood test)* şi sigmoidoscopia flexibilă în detectarea cancerului şi a neoplaziilor avansate (10,14, 17, 18).

Istoricul familial de CCR este un factor de risc bine cunoscut în apariţia bolii, ghidurile actuale recomandând screening-ul colonoscopic la rudele de grad I a pacienţilor diagnosticaţi cu CCR (9-11).

Prin urmare, noi am adoptat colonoscopia ca metodă de screening în studiul nostru şi am avut o rată de participare de 27,1%. Studii similare din străinătate raportează o rată de participare între 30% şi 40% (19, 20). Ruthotto si colab. (21) raportează că mai puţin de 40% din rudele de grad I a pacienţilor cu CCR au acceptat să participe la un program de screening colonoscopic, sugerând că informarea pacienţilor despre riscul potenţial de apariţie a bolii la rude determină creşterea ratei de participare la screening. Studii similare din ţară (22) au demonstrat că screening-ul prin colonoscopie al rudelor pacienţilor cu CCR reprezintă o metodă fezabilă şi sigură pentru depistarea polipilor colorectali şi CCR.

În studiul nostru am depistat 45 de leziuni la 36 pacienţi (28,8%), dintre care adenoame la 20,8% şi polipi non-neoplazici în 7,2% din cazuri; în plus, am depistat un caz de adenocarcinom (0,8%). Constatările noastre confirmă rezultatele altor studii (23--25). Astfel, Pezzoli şi colab. (23) raportează adenoame depistate în 21,7% din cazuri, iar Colombo şi colab. (20) - adenocarcinoame în 0,9%. Pe de altă parte, am găsit un procent ridicat de adenoame avansate – 11,2% dintre cazuri, considerate a fi factori

de risc importanţi în dezvoltarea CCR. Rezultate similare raportează Pariente şi colab. (19) în ce priveşte prevalenţa adenoamelor avansate. Se poate specula că factorii genetici influienţează viteza de creştere a adenomului, mai degrabă decât numărul lor. Această ipoteză este susţinută în studiul publicat de Fossi şi colab. (26) în privinţa timpului de reapariţie a adenoamelor la rudele de grad I a pacienţilor cu CCR.

Intubarea cecală s-a reuşit în 96% din cazuri, atingând aceleaşi cote ca şi în alte centre de endoscopie performante (27).

CONCLUZII

Rudele de grad I a pacienţilor cu CCR sunt mai predispuşi la dezvoltarea adenoamelor avansate decât populaţia generală. Colonoscopia este o metoda eficientă şi fezabilă de screening pentru CCR la rudele pacienţilor cu această boală malignă.

NOUTĂŢI

Tratamentul HTA are efecte favorabile asupra riscului de fibrilaŢie atrială

Hipertensiunea arterială esenţială acţionează asupra întregului sistem cardiovascular putând induce printre altele o hipertrofie ventriculară stângă ce antrenează o disfuncţie diastolică a ventricolului stâng, asociată unor tulburări de ritm ventriculare şi atriale, astfel încât riscul de fibrilaţie atrială este în general mai crescut la subiecţii hipertensivi. O serie de medicamente antihipertensive acţionând asupra remodelajului cardiovascular, cu precădere asupra celui atrial (de exemplu prin inhibarea sistemului renină-angiotensină-aldosteron), par a împiedica apariţia unei fibrilaţii atriale. Un studiu intracohortă de tip caz-martor, de mare anvergură, aduce argumente în favoarea acestei ipoteze. Datele au fost extrase dint-o bază de date (General Practice Research Database) ce numără teste cinci milioane de observaţii raportate de medicii generalişti englezi. În total, 4 661 de pacienţi hipertensivi având şi fibrilaţie atrială (FA) au fost comparaţi cu 682 993 de pacienţi martori, trataţi pentru hipertensiune arterială (HTA), riscul de FA fiind estimat în funcţie de tratamentul antihipertensiv : betablocante, inhibitori ai enzimei de conversie (IEC), antagonişti ai receptorilor de angiotensină II (ARA II). În grupul martor au fosr reţinuţi pacienţi trataţi cu inhibitori calcici care nu influenţează tulburările de ritm cardiac. De asemenea, au fost excluşi subiecţii ce prezentau factori de risc pentru FA. Analiza comparativă a aratat că riscul relativ de FA (odds ratio – OD) a fost mult mai redus la pacienţii trataţi comparativ cu lotul martor : IEC (OD=0,75), ARA II (OD=0,71), betablocante (OD=0,78) (Schaer BA et al. Risk for incident atrial fibrillation in patients who receive antihypertensive drugs : a nested case–control study. *Ann Intern Med* 2010 ; 152 : 78-84).

IMPLICATIONS OF VITAMIN D DEFICIENCY IN INFLAMMATION DUE TO RHEUMATOID ARTHRITIS (Abstract): Chronic inflammation due to inflammatory joint diseases, the most important of which is rheumatoid arthritis, is a both topical and overall bone loss risk factor. There have been numerous researches showing that vitamin D plays a major role in inflammation by stimulating innate immunity, and also by boosting its activity and by decreasing adaptive immune activity. In our research, we analyzed the factors involved in bone mass loss in patients suffering from rheumatoid arthritis, as well as the link between the serum level of 25 (OH) vitamin D and the extent of the inflammation. We also tackled the impact of vitamin D supplement delivery on the status of these patients. **Keywords:** RHEUMATOID ARTHRITIS, 25 (OH) VITAMIN D, INFLAMMATION.

Inflammation is closely linked to significant fracture risk (1, 2) in chronic inflammatory conditions, such as rheumatoid arthritis (3, 4) or ankylosing spondylitis, as well as when a low degree of inflammation is detected in apparently healthy individuals.

Rheumatoid arthritis is one of the most important inflammatory conditions since in addition to its triggering local juxta-articular bone impairment, it also entails bone mass loss at considerable distances from the joints (5). In rheumatoid arthritis the bone is a major target for chronic inflammation, this condition being caused by the numerous interactions and interconnections between the bone and the immune system (6). Inflammation occurring in the bone leads to bone resorption increase and it determines local bone formation suppression (7, 8).

Research in this field has shown that juxta-articular bone mass loss and bone inflammation occur during the early stages of the disease and that they precede and are also predictive of erosive bone destruction specific to rheumatoid arthritis (9). A European multi-center study published in 2017 revealed that patients with rheumatoid arthritis usually exhibit vitamin D insufficiency or even deficiency, with significant differences among various coun-

tries. The serum levels of vitamin D in the patients included in this study were inversely proportional to life quality indices, to the stage of the disease and to the degree of disability (10).

MATERIAL AND METHODS

The observational prospective case-control study was carried out for about one year, from January 2017 to January 2018.

The research was aimed at analyzing the factors involved in bone mass loss in patients with rheumatoid arthritis, as well as at determining the connection between the serum level of 25OH vitamin D and the extent of the inflammation, and also the impact of vitamin D supplement delivery on the status of these patients.

There were initially 93 patients with rheumatoid arthritis included in the study, who were selected based on the inclusion criteria set in the study protocol (20 to 65 years of age, confirmed rheumatoid arthritis diagnosis in various disease evolution stages: I, II or III), but also according to the exclusion criteria (less than 20 or more than 65 years of age, related diseases – endocrine or neoplastic conditions). Only 82 patients were left in the study group after reassessment.

Patient data (personal and family medical history), anthropometric indices (weight, height, BMI), data on socio-demographic factors and life style (exercise, active smoking) and data on clinical parameters (number of painful joints, number of swollen joints, morning stiffness) were collected on the initial assessment. Patients were also selected depending on the rheumatoid arthritis stage and maintenance therapy administered before.

A series of biological parameters of inflammation, such as ESR (erythrocyte sedimentation rate) and CRP (C reactive protein), as well as certain biological parameters assessing the possible complications of the basic disease or side effects of the maintenance therapy, among which certain hematological, hepatic or renal factors, were also determined in order to set the stage of the disease. Also, in this study, we dosed 25-OH vitamin D in order to determine whether mild or severe vitamin D deficiency is linked with the extent of bone mass loss, with the level of pain and possibly with the level of disease activity and degree of disability. We calculated internationally acknowledged scores (DAS 28, HAQ, SDAI, CDAI) for all the patients included in the study, in order to be able to assess the level of disease activity and degree of disability. The immunological markers of the disease were determined in all the patients: rheumatoid factor (RF), anti-citrullinated protein antibodies (ACPA), total antinuclear antibodies (ANA), using Elisa-type tests.

On the 6-month follow-up, we analyzed the inflammation parameters again (ESR, CRP), we studied the new values of the immunological markers (rheumatoid factor, ACPA), and we calculated the new internationally-used disease activity scores (DAS 28, CDAI, SDAI, HAQ), in order to be able to monitor disease activity dynamics and its functional impact.

Throughout the study, all the patients underwent classical or biological DMARDs therapy. After their initial assessment, 95% of the patients also received vitamin D supplements and this was decided since we found significant vitamin D deficiency in the patients included in the study.

RESULTS

The number of painful joints was 0 to 24, and the value series median was 6. The results of the Skewness test suggest that

NPJ (number of painful joints) is a continuous variable (p=0.851).

The mean NPJ was 7.46±6.53, i.e. significantly lower than the number of painful joints before the treatment – 8.77±7.67 joints (p=0.001).

The NSJ (number of swollen joints) was 0 to 16, and the value series median was 1, whereas the mean was 2.11, and the results of the Skewness test suggest that NSJ is a discontinuous variable (p=2.488), which restricts the application of parametric significance tests. On reassessment, the mean NSJ was 2.11±0.36, i.e. significantly lower than the number of swollen joints detected before therapy –2.46±0.48 joints (p=0.037).

Pain VAS (visual analogue scale) ranged between 1 and 8. The value series median was 4, i.e. close to the mean value of 4.01. The results of the Skewness test suggest that the VAS value series was homogeneous (p=0.266). On reassessment, the mean VAS was 4.01±2.22, which was significantly lower than the VAS determined at the beginning of the study, which was 4.70±2.44 (p=0.001) (fig. 1).

In the patients included in the research, the disease activity score DAS_{28} had normal distribution (p= -0.026), ranging from 2 to 7 and exhibiting a value series median of 4.03. The second assessment revealed a mean DAS_{28} of 3.97±1.39, which was slightly lower than the score recorded during the first assessment, which was 3.99±1.52 (p=0.813) (fig. 2).

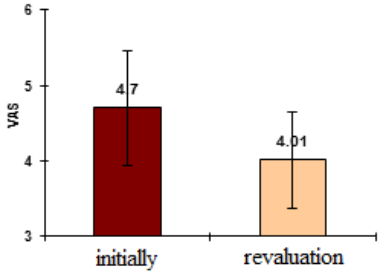

Fig. 1. Evolution of mean VAS

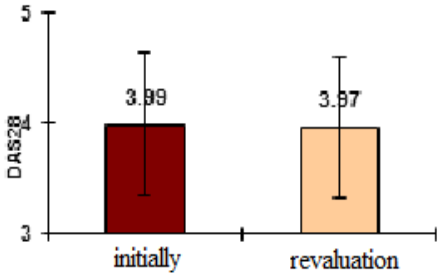

Fig. 2. Evolution of mean DAS_{28}

On reassessment, the ESR ranged from 4 to 115 mm/h, with a homogeneous value series (p=1.259), the mean reading being 34.39±22.25 mm/h, without being significantly different from the initial one of 34.18±22.25 mm/h (p=0.834) (p=0.834).

On reassessment, the CRP showed wide variations within the 0.40-102 mg/dl range, the mean level being 7.28±8.63 mg/dl, i.e. slightly lower than the reading at the beginning of the research 7.55±4.06 mg/dl (p=0.710).

Of all the clinical parameters, only VAS varied significantly depending on Latex rheumatoid factor positivity (4.39 *vs.* 3.39; p=0.046).

The mean level of clinical parameters did not show significant differences depending on Waller Rose rheumatoid factor positivity, with the exception of VAS (4.39 *vs.* 3.39; p=0.046).

The rheumatoid factor tested positive especially in the female sex (p=0.247) and in the urban environment (p=0.582), but the percentage distributions were not statistically significant. 46.9% of the high titre patients and 73.3% of the low titre patients were 60 and older, whereas 63.6% of the

negative titre patients had not reached this age (p=0.039).

Serum calcium and ESR were apparently independent parameters both at the beginning of the study (r= -0.004; p=0.973) and on reassessment (r= -0.068; p=0.546) (fig. 3).

Vitamin D values showed negative correlation with both VAS and HAQ, both on the first assessment and on reassessment.

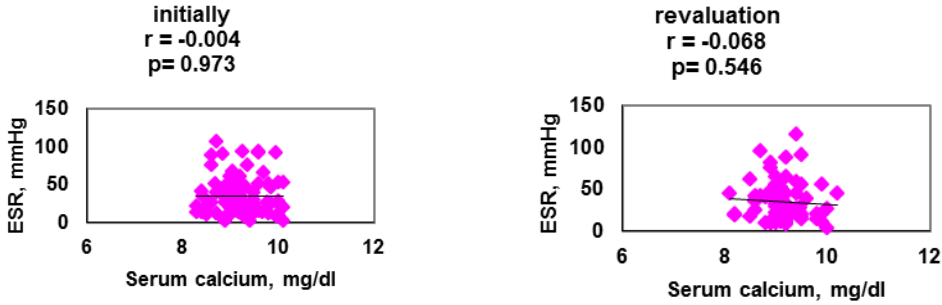

Fig. 3. Serum calcium correlation with ESR

The vitamin D and ESR correlation was indirect and weak, both at the beginning of the study (r= -0.146; p=0.169) and on reassessment (r= -0.169; p=0.130) (fig. 4).

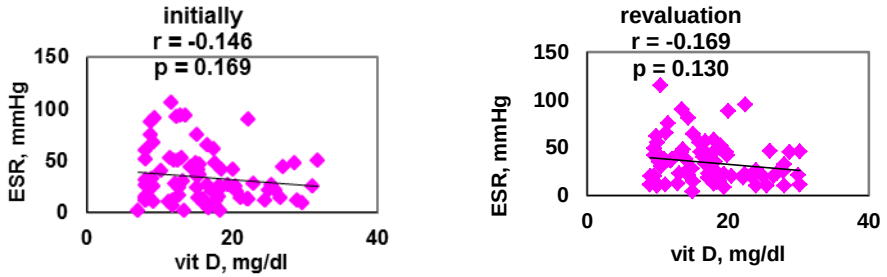

Fig. 4. Vitamin D and ESR correlation

On the first assessment, the lower vitamin D and serum calcium levels were associated with higher ESR values. (fig.5).

On the other hand, on reassessment, the higher vitamin D and serum calcium levels were associated with lower CRP values. (fig.6)

Vitamin D and CRP were also apparently independent parameters both at the beginning of the study (r= -0.017; p=0.881) and on reassessment (r= +0.026; p=0.814) (fig.7).

At the beginning of the study, 21% of the patients had higher serum calcium values and higher white cell counts (r= +0.210; p=0.05), whereas on reassessment only 15.5% of them still exhibited this characteristic (r= +0.155; p=0.165). Nevertheless, these findings cannot be extrapolated to the general population.

DISCUSSION

A study published in 2018 revealed that low vitamin D values in the serum were associated with a series of autoimmune diseases. This research revealed a negative correlation of serum 25 (OH) vitamin D concentrations with pain and disease activity score in patients with rheumatoid arthritis, yet it was unable to clearly determine the cause-effect relation. The same research found that vitamin D supplements were associated with significant effects on pain and on disease activity in patients suffering from rheumatoid arthritis. It was also found that vitamin D deficiency seems to be tightly connected to pain, whereas high serum concentrations of 25 (OH) vitamin D seem to have immunomodulating effects (11, 12).

On reassessment, the analysis of our group of patients showed a significantly lower mean NPJ level compared to the number of painful joints detected in the patients at the beginning of the research, which proves a positive evolution of pain, correlated with improved 25OH vitamin D levels. This also stands for a mean NSJ level.

On reassessment, the mean VAS level was significantly lower than the VAS determined before the therapy, and it was also correlated with 25 (OH) vitamin D values. 6 months after the beginning of the study, the mean DAS_{28} of these patients was slightly lower than the one determined on the first assessment. The VAS scale on reassessment improved and it was correlated with improved NPJ and NSJ values, as well as with 25 (OH) vitamin D values.

The vitamin D and ESR correlation was indirect and weak, both at the beginning and on reassessment. On the first assessment, the lower vitamin D and serum calci-

um levels were associated with higher ESR values. On reassessment, the higher vitamin D and serum calcium levels were associated with lower CRP values.

Negative correlations of the vitamin D level with the pain and disability scales were detected.

CONCLUSIONS

The assessment of the patients 6 months after the beginning of the study showed a slight improvement of the inflammatory and immunological syndrome, knowing that in addition to their anti-inflammatory maintenance therapy they were also given vitamin D supplements.

Our research showed that strong inflammation was linked to lower vitamin D and serum calcium levels, especially on the first assessment.

The findings of our study are in line with the research in the field, as they reveal that the intake of vitamin D supplements since the onset or since the early stages of rheumatoid arthritis may lead to an improvement of these patients' status, both from the viewpoint of joint and muscle pain and of mobility and stability improvement, and from the viewpoint of bone mass loss slowdown.

RECONSIDERING STATINS-CURRENT VIEW (Abstract): Statins are widely used in daily clinical practice for the management of dyslipidemia. There are numerous studies that have shown a pleiotropic effect of statins in chronic liver diseases. They increase nitric oxide synthesis, restore endothelial cell function and, by that, increase the number of progenitor endothelial cells which improve endothelial function. Simvastatin lowers portal pressure in patients with cirrhosis and portal hypertension by reduction of hepatic vascular resistance without adverse effects on systemic circulation and with an excellent safety profile. Simvastatin addition to standard therapy in patients with cirrhosis who recover from an acute variceal bleeding episode improves survivability. Statins modulate intrahepatic vascular tone and by that improve liver function and lack of significant hepatotoxic effects. Statins inhibit protease pathway activation, exert anti-inflammatory and immunomodulatory effects, modifying the cell activation cascade. Due to all these mechanisms, statins have antineoplastic effects.
Keywords: STATINS, LIVER CIRRHOSIS, VIRAL HEPATITIS, HEPATOCARCINOMA.

Statins are widely used in daily clinical practice for the management of dyslipidemia. More than half of the patients aged over 75 and one third of the patients aged 40 use that medication to lower their cholesterol level.

On the other hand, it is well known that statins have been associated with potential liver toxicity with increased liver enzymes.

However, evidence suggests a safe and beneficial effect of this "forbidden" drug which became a "magic pill" in almost every liver disease: hepatitis, portal hypertension, cirrhosis, hepatocellular cancer (HCC), nonalcoholic fatty liver disease/nonalcoholic steatohepatitis (NAFLD/NASH) (tab. I).

There are numerous studies that have demonstrated the pleiotropic effects of statins in chronic liver diseases. Statins act by inhibiting the activity of 3-hydroxy-3methyguaryl coenzyme A reductase (2, 3). Secondary to lipid lowering effect, this mechanism has as consequence the decrease of oxidative stress and inflammation by decreasing the activation of inflammatory cells. Consequently, they increase nitric oxide synthesis, restore endothelial cell function and, by that, increase the number of progenitor endothelial cells which improve endothelial function (4, 6).

In vitro studies have also suggested a favorable impact on hepatic inflammation, progression of fibrosis and hepatic vascular tone (7, 8). The effects on fibrosis progression and hepatic decompensation in patients with chronic liver disease reported in some recent studies (9,10) were very variable.

TABLE I
Properties of statins associated with observed benefits in liver disease
Adapted after (1)

LIVER DISEASE	STATIN PROPERTIES
NAFLD/NASH	LDL cholesterol reduction Reduced inflammation Reduced fibrosis Antioxidant properties
Hepatitis C	Reduction of hepatitis C virus replication
Portal hypertension	Increase in NO bioavailability Reduction in collagen production Inhibition of hepatic stellate cell activation
HCC	Inhibition of proliferation Increased apoptosis
Cirrhosis	Reduction in portal hypertension Reduction of collagen production Reduction in inflammation

Statins and portal hypertension in liver cirrhosis

The degree of portal hypertension is determined by hepatic venous pressure gradient (HVPG). Studies and meta-analyses have shown that prognosis of cirrhotic patients improve when HVPG decreases >20% from baseline or to a level lower than 12 mmHg. Less than half of patients receiving β-blockers achieve this target. Moreover, about 15% of patients have contraindications and an additional 15% may not tolerate.

This has prompted an alternative drug for long term treatment of portal hypertension (11, 12).

An ideal drug for portal hypertension was pictured as one that should reduce portal pressure acting as a hepatic vasodilator by decreasing intrahepatic vascular resistance and maintaining or enhancing hepatic blood flow.

Simvastatin and atorvastatin exert their hepatic vasodilatation effect by up-regulating endothelial NO production and act as true liver-selective vasodilators because blood pressure and systemic vascular resistance were unchanged after continuous use. This is totally different from the mechanisms mediating the effects of β-blockers, which reduce HVPG through a decrease in Porto collateral blood flow. The different mechanism of action probably explains the additive effect of simvastatin and β-blockers on HVPG (13, 14).

According to a randomized controlled trial conducted by Abraldes *et al.* (15), simvastatin lowers portal pressure in patients with cirrhosis and portal hypertension.

The study had a randomized two-group design; one group received simvastatin for 1 month, 20 mg/day for the first 15 days, 40 mg thereafter, and the other group received placebo with or without propranolol treatment prior to the study. The authors found that after one-month simvastatin significantly decreased HVPG in patients with cirrhosis and severe portal hypertension. Simvastatin reduced HVPG by 10% or more in 40% of patients, to a value to protect against bleeding in early portal

hypertension (HTP).

In 32% of patients it was recorded a reduction in HVPG of ≥ 20% from baseline. Moreover, the HVPG-decreasing effect of simvastatin is independent of concomitant treatment with β-blockers, because β-blockers determine on average a reduction in HVPG of 10-15%; the additive effect of simvastatin increases the number of patients who are protected effectively against the complications of portal hypertension. In conclusion, the authors summarize that simvastatin lowers portal pressure in patients with cirrhosis and HTP, by reduction of hepatic vascular resistance without adverse effects on systemic circulation and with an excellent safety profile. Another beneficial effect observed in this study was that simvastatin decreases HVPG in patients taking/not taking β-blockers, suggesting that its effect on portal hypertension is additive. Unlike β-blockers, simvastatin improves quantitative liver function test results by enhancing liver perfusion, thus providing additional benefits in cirrhosis. These effects of simvastatin indicate that it has a clear potential for the treatment of HTP in patients with cirrhosis. Adding to the fact that propranolol is contraindicated in severe circulatory dysfunction or severe refractory ascites. Future trials should evaluate whether these critically ill patients are good candidates for statins.

None of the patients in the study who received simvastatin had an increase in liver aminotransferase levels. Moreover, the authors observed a slight improvement in liver function. Statin hepatotoxicity in cirrhotic patients does not seem to be higher than that in the general population.

In conclusion, the study reinforces the promising role of simvastatin in decreasing portal hypertension and improving liver function. Prophylaxis of variceal hemorrhage associated with portal hypertension is a new indication for simvastatin. Critically ill patients (severe circulatory dysfunction or refractory ascites) may be good candidates.

In a multicenter, double-blind, randomized trial (17), addition of simvastatin to standard therapy did not reduce rebleeding but was associated with a survival benefit in patients with Child class A or B cirrhosis. The cirrhotic patients with variceal bleeding receiving simvastatin had a longer survival compared to those receiving placebo. In the cirrhotic patients who recovered from an acute variceal bleeding episode, the addition of simvastatin to standard therapy (β-blockers and ligation) improved survival rate without reducing the rate of other complication. The authors conclude that simvastatin addition to standard therapy in cirrhotic patients who recover from an acute variceal bleeding episode improves survivability. Beneficial effects may be mostly due to the increased hepatic blood flow and consequent improvement in liver function. Although unable to prevent these complications, simvastatin attenuated the deleterious effect of these events and did not increase their rate.

Statins and Hepatitis C compensated cirrhosis

Between 1996-2009, Mohanty *et al.* (18) conducted a cohort study of 40512 patients with HCV-related compensated cirrhosis. They identified 2802 statin users. The study demonstrated a 40% lower risk of decompensation and death in HCV-related compensated cirrhosis in patient who were using statins. The beneficial effects of statins in this study were the reduction of portal pressure in patients with

cirrhosis, improved survival without effect on recurrent bleeding. Beside these, an important effect was that statins modulate intrahepatic vascular tone and by that improve liver function and lack of significant hepatotoxic effects. By these effects, statins reduce the risk of decompensation and death in hepatitis C-related compensated cirrhosis.

Statins and infections in liver cirrhosis

In a study on veterans with cirrhosis, Motzkus-Feagans *et al.* (19) demonstrated that statins provided a protective effect against infections compared with non-users of any cholesterol-lowering medications. Statin use has been associated with a decreased risk of pneumonia and other severe infections, sepsis included. The involved mechanism is explained by the anti-inflammatory properties of statins.

Statins are associated with reduced risk of hepatocellular carcinoma

In a meta-analysis of ten studies including over 1,400,000 patients of which 4298 had hepatocellular carcinoma (HCC), Sigh *et al.* (20) found that statin use is associated with a 37% reduction in the risk of HCC. This effect was more pronounced in the Asian population.

Statins inhibit the activation of protease pathway, exert anti-inflammatory and immunomodulatory effects, modifying the cell activation cascade. Due to all these mechanisms, statins have antineoplastic effects.

There is a difference between Asian and Western population with respect to the chemo preventive effects of statins in HCC. Chronic HVC infection is the dominant risk in Asia and sub-Saharan Africa, whereas in USA and Western countries, alcohol, HCV, NAFLD associated with obesity and metabolic syndrome are responsible for liver cancer. Statins in Asian population exert their effect by antagonizing the oncogenic effect of HBV; the mechanisms by which statins alter the risk of HCC in Western population is not clear (the protective effect may be related to modification of metabolic syndrome insulin-mediated cell proliferation and obesity- associated inflammation).

Additionally, because patients with HCV infection are at higher risk for type 2 diabetes mellitus, statins may exert their antineoplastic effects through anti-infective properties.

The studies have shown that the chemo preventive effects are greater with higher dose. Tsan *et al.* (21) analyzed a cohort of patients with hepatitis B. They found that a high dose duration of statins was associated with greater protective effects on HCC. In line with this study, the study conducted by El Serag *et al.* (22) noticed that statin use for more than 6 months was associated with a significant decrease in the risk of HCC. A significant dose-response relationship between statin use and development of cancer has not been demonstrated yet. Statins have been shown to have a proangiogenic effect at low doses and an antiangiogenic effect at high doses in *in vivo* studies (23).

Lipophilic statins (lovastatin, simvastatin) may have a greater chemo preventive effect than lipophobic statins (pravostatin) due to a greater lipid solubility and membrane permeability (24).

CONCLUSIONS

Our review highlighted the role of statins in in hepatic diseases. Statins lower portal pressure in patients with cirrhosis and portal hypertension. In cirrhotic patients who recover from an acute variceal

bleeding episode statin in addition to standard therapy improve survivability. Due to their anti-inflammatory properties, statins decrease the risk of pneumonia and other severe infections, sepsis included, in liver cirrhosis. Statins improve liver function, lack significant hepatotoxic effects and have antineoplastic effects.

We strongly recommend reconsidering statins use in chronic liver diseases.

NEWS

SUDDEN UNEXPECTED DEATH IN EARLY PARKINSON'S DISEASE: NEUROGENIC OR CARDIAC DEATH?

The histological hallmark of idiopathic Parkinson's disease (PD) is Lewy pathology (LP), including Lewy bodies in cell somata and thread-like Lewy neurites, both composed primarily of phosphorylated α-synuclein. Recent clinicopathological studies have revealed that individuals with PD show various nonmotor signs. These nonmotor signs are also related to the deposition of phosphorylated α-synuclein and tend to appear earlier than the typical motor signs. An individual with LP who has not yet developed typical motor signs is considered to have premotor PD. The authors presented two cases of sudden unexpected death (SUD) in elderly individuals in whom autopsy unexpectedly showed Lewy pathology, a hallmark of Parkinson's disease. Both individuals were 68-year-old men who were found dead in their homes without lethal trauma or poisoning. Inquests into their deaths suggested that nonmotor cardiovascular signs of Parkinson's disease might have appeared just before their deaths, although few typical motor signs were present. Autopsy showed Lewy pathology in the heart and peripheral autonomic nervous system in addition to lesser involvement of the brainstem that was consistent with Braak stage 3. In case 1, an atrial septal defect of the secundum type with advanced fibrosis of the atrium was present. In case 2, severe stenosis of the atrioventricular node artery with some microscars and diffuse interstitial fibrosis of the basilar ventricular septum were found. These two cases show some premotor Parkinson's disease with a symptom suggestive of autonomic dysregulation which may be a risk of SUD. In addition, coexistence of structural change of the heart with possibly arrhytthmogenic potential may increase the risk of SUD with Parkinson's disease. At present, very few pathological reports have included detailed cardiac pathology of SUD in patients with PD. Here, the authors presented the cases of two elderly men with SUD whose autopsies showed unpredicted LP. So, autonomic dysfunction related to PD has been considered a major contributor to sudden unexplained death (SUD) in patients with PD (Nishida N, Yoshida K, Hata Y. Sudden unexpected death in early Parkinson's disease: neurogenic or cardiac death? *Cardiovascular Pathology*, 2017, 30: 19-22).

DIAGNOSIsAND THERAPEUTIC ASPECTS OF ISOLATED SYSTOLIC HYPERTENSION (Abstract): The isolated systolic hypertension is a distinct entity concerning evolving, pathological, diagnosis and treatment particularities. The present study analyzed the behavior of the blood pressure by continuous ambulatory monitoring of a group of patients diagnosed with isolated systolic hypertension by office measurement. **Material and method**: One hundred and twenty nine patients with isolated systolic hypertension at office were included. They were subjected to continuous ambulatory monitoring of blood pressure, then the treatment was started. After six months the patients were reassessed. **Results**: Continuous ambulatory monitoring better indicates the increase of systolic tension and the reduction of the diastolic tension by aging. The pulse pressure is significantly higher at the over sixty-five group. The systolic tension is directly correlated with the pulse pressure and indirectly with the diurnal index. ($r = 0.36$). After six months of treatment the reevaluation shows a statistically significant reduction of the pathological parameters although without achieving tensional control. **Conclusions**: The ambulatory monitoring better highlights the values of hypertension and assesses the LOAD and Day Index values. Achieving the therapeutic goal regarding systolic hypertension proves difficult. **Key words**: ISOLATED SYSTOLIC HIPERTENSION, AMBULATORY BLOOD PRESSURE MONITORING

Hipertensiunea sistolică izolată (HSI) este prevăzută ca entitate patologică distinctă de noile ghiduri, fiind definită ca şi creştere a TA sistolice ≥140 mmHg, pe când TA diastolică este < 90 mmHg (1,2). Gradarea se efectuează identic cu HTA sistolodiastolică, însă se ţine cont numai de valoarea TA sistolice. TA sistolică este cel mai puternic factor de risc cardiovascular la bărbaţi vârstnici şi la femei de orice vârstă.

HSI prezină particularităţi patogenice, evolutive şi terapeutice (3). Istoria naturală, în absenţa intervenţiei terapeutice, predispune la creşterea progresivă a TA sistolice odata cu înaintarea în vârstă şi reducere moderată a TA diastolice, ceea ce accentuează TA diferenţială, adică presiunea pulsului. Acest ultim parametru constituie factor de risc independent la pacienţii peste 65 de ani, conform Ghidului European de Hipertensiune Arterială.

Paternurile hipertensive se modifică odată cu vârsta. Astfel, dacă ne referim la HTA esenţială, la tineri regula o reprezintă hipertensiunea sistolo-diastolică însă, după vârsta de 50 de ani, prevalenţa hipertensiunii sistolice izolate creşte progresiv şi

devine predominantă după vârsta de 65 de ani (4,5).

OBIECTIVELE STUDIULUI

Am efectuat un studiu prospectiv observaţional, care a urmărit comportamentul hipertensiunii arteriale prin monitorizare continuă ambulatorie la un lot de pacienţi diagnosticaţi cu hipertensiune sistolică izolată la determinarea de cabinet.

MATERIAL ŞI METODĂ

Lotul de studiu a fost constituit din 129 de pacienţi monitorizaţi în perioada ianuarie 2007 – octombrie 2008.

Sub aspect terapeutic au fost luaţi în consideraţie pacienţii cu :

1) HTA nou diagnosticată ;

2) HTA cunoscută în antecedente dar netratată ;

3) HTA sub tratament dar necontrolată, fără „perioadă de spălare" (washout) ;

4) Hipotensiunea arterială simptomatică.

Pentru fiecare subiect s-au efectuat anamneză şi examen clinic complet, cu măsurarea TA manual în clino si ortostatism, după care s-a montat sistemul de monitorizare continuă a TA la nivelul membrului nondominant.

Sistemul de monitorizare pe care noi îl utilizăm se numeşte ABPM-04, care corespunde cerinţelor protocolului de validare British Hypertension Society (BHS) referitor la tensiometrele automate. Acest dispozitiv utilizează programul MediBase pentru vizualizare şi pentru prelucrarea statistică a datelor. Aparatul înregistrează tensiunea arterială sistolică, tensiunea arterială diastolică, presiunea medie şi frecvenţa centrală din 15 în 15 minute în intervalul diurn (6 – 22) şi din 30 în 30 de minute în perioada pasivă, conform programării de către medic. Rezultatele sunt afişate ca valori medii, maxime şi minime pe 24 de ore, pe perioada activa şi pe cea pasivă. Softul calculează indicele diurn (ID), indicele de hipertonie (PTE), încărcare hiperbară (LOAD) pentru tensiunea sistolică, diastolică şi medie. Pentru frecvenţa cardiacă şi pentru presiunea pulsului se calculează valorile maxime, minime şi medii pe 24 de ore, ziua şi noaptea.

Metode statistice aplicate au fost : testul t-Student, testul $\chi 2$, coeficientul de corelaţie "Pearson" (r), coeficientul de variaţie (CV%). Datele au fost încărcate şi prelucrate cu ajutorul funcţiilor statistice din EPIINFO şi EXCEL.

REZULTATE

CARACTERISTICI EPIDEMIOLOGICE

Lotul de studiu a fost constituit din 129 pacienţi, 102 femei şi 27 bărbaţi în raportul F/M = 3,37/1. Distribuţia pe sexe a fost în favoarea sexului feminin (79,1%).

Distribuţia pe grupe de vârstă a fost stabilită la data primei investigaţii şi se prezintă astfel : vârsta medie a pacienţilor la intrarea în studiu a fost de 66,23 ± 10,69 ani, variind între 18 şi 93 ani.

Pe sexe, vârsta medie a cazurilor de sex feminin a fost de 66,13 ani cu variaţii de la 18 la 93 ani, iar la sexul masculin vârsta medie a fost de 66,23 cu variaţii de la 51 la 82 ani, fără a se înregistra diferenţe semnificative din punct de vedere statistic între sexe (t = 0,05 ; GL = 127 ; p=0,972).

Se observă o distribuţie crescută a cazurilor la grupa de vârstă 71-80ani (34,9%), urmată de grupele de vârstă 61-70 ani

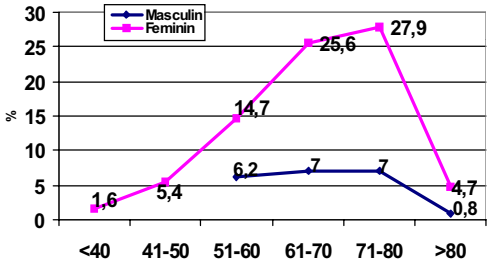

Fig. 1. Distribuţia pe grupe de vârstă şi sex la pacienţii cu tensiune sistolică izolată

TABELUL I
Valori medii ale tensiunii arteriale la lotul de studiu

Tensiune arterială	Cabinet	Medie 24 ore	Minimă	Maximă
TAS	170,64±15,87	152,33±9,83	118,71±13,97	194,29±15,25
TAD	82,475±5,93	72,39±8,74	50,74±8,74	104,40±16,51

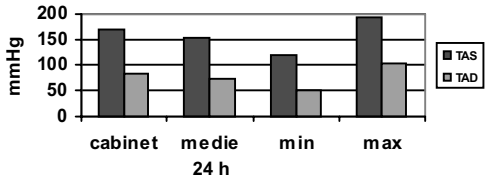

Fig. 2. Valori medii ale tensiunii arteriale la pacienţii cu tensiune sistolică izolată

(32,6%) şi 51-60 ani (20,9%).

Pe grupe de vârstă şi sex, modulul se întâlneşte la sexul feminin la grupa de vârstă 71-80 ani, iar la sexul masculin o distribuţie bimodală la grupele de vârsta 61-70 şi 71-80 ani.

Valorile medii măsurate la cabinet cât şi mediile pe 24 de ore relevă aspectul de hipertensiune sistolică izolată la întreg lotul de studiu.

Pe grupe de vârstă se observă creştere tensiunii arteriale sistolice şi scăderea tensiunii arteriale diastolice odată cu înaintarea în vârstă.

Pe grupe de vârstă nu s-au înregistrat diferenţe semnificative statistic ale tensiunii arteriale sistolice măsurate brahial însă valorile medii măsurate prin monitorizare continuă relevă mai fidel creşterea tensiunii arteriale sistolice şi reducere uşoară a tensiunii diastolice la vârstnici.

PRESIUNEA PULSULUI

Monitorizate pe grupe de vârstă valorile medii depăşesc 50 mmHg la ambele grupe şi sunt semnificativ mai mari la vârste de peste 65 ani ($t = 3,49$; $GL = 127$; $p < 0,001$) :

- ≤ 65 ani : $58,85 \pm 10,66$ mmHg
- > 65 ani : $65,79 \pm 11,72$ mmHg.

Distribuţia de frecvenţe ale pacienţilor cu valorile presiunii pulsului peste 50 mmHg relevă ca fiind factor de risc pentru vârstnici ($\chi^2 = 6,11$; $GL = 1$; $p = 0,013$). Valoarea predictivă ca un pacient cu vârsta peste 65 ani să aibă presiunea pulsului peste 50 mmHg este de 63%.

Indexul diurn s-a monitorizat atât pentru tensiunea arterială sistolică cât şi pentru tensiunea arterială diastolică şi MAP.

Analizând această distribuţie se observă că cele mai mari frecvenţe a pacienţilor revers dipper şi non dipper se întâlnesc la tensiunea arterială sistolică şi de aceea în prelucrare vom ţine cont numai de indexul diurn al TAS.

Indexul diurn nu a diferit semnificativ în funcţie de sex ($\chi^2 = 0,81$; $GL = 3$; $p = 0,847$) însă prezintă diferenţe semnificative pe grupa de vârstă ($\chi^2 = 7,81$; $GL = 3$; $p = 0,05$).

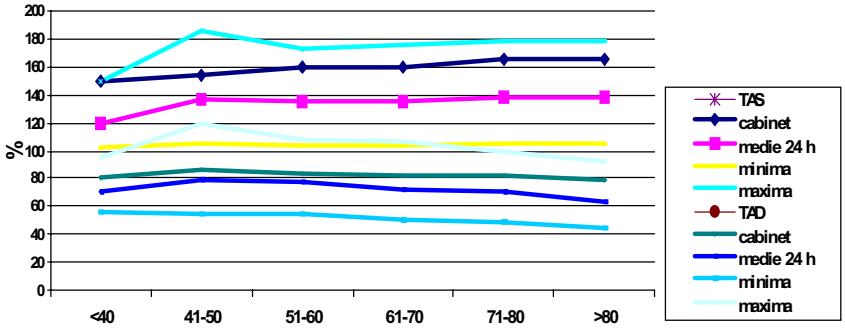

Fig. 3. Distribuţia valorilor tensiunii arteriale pe grupe de vârstă

TABELUL II

Diferenţe ale valorilor medii tensionale în funcţie de grupe de vârstă la pacienţii cu hipertensiune sistolică izolată

Parametru	TAS	
	Cabinet	Medie 24 ore
≤65 ani (n=53)	171,52±14,49	150,52±9,09
>65 ani (n=76)	170,0±16,99	153,63±10,28
Semnificaţie statistică	t = 0,36 p>0,05	t = 1,18 p>0,05
Parametru	TAD	
	Cabinet	Medie 24 ore
≤65 ani (n=53)	82,58±10,66	72,07±9,47
>65 ani (n=76)	81,91±7,63	71,44±9,54
Semnificaţie statistică	t = 0,69 p>0,05	t = 0,03 p>0,05

TABELUL III

Distribuţia de frecvenţe a indexului diurn la pacienţii cu tensiune sistolică izolată

Index diurn	**TAS**		**TAD**		**MAP**	
	N	**%**	**n**	**%**	**n**	**%**
revers dipper	36	27,9	12	9,3	18	14,0
non dipper	61	47,3	51	39,5	61	47,3
dipper	27	20,9	51	39,5	42	32,6
hiper dipper	5	3,9	15	11,6	8	6,1

Indicele de hipertonie (PTE) a fost monitorizat atât pentru tensiunea arterială sistolică cât şi pentru tensiunea arterială diastolică şi MAP. Se observă cele mai mari frecvenţe ale acestui parametru tot pentru TAS.

Valorile medii nu diferă semnificativ între sexe sau grupe de vârstă.

SARCINA DE PRESIUNE (LOAD)

Distribuţia de frecvenţe a sarcinii de presiune analizată în funcţie de sexul (χ^2 = 1,17; GL = 2; p = 0,558) şi vârsta pacientului (χ^2 = 2,74; GL = 2; p = 0,257) nu relevă diferenţe semnificative din punct de vedere statistic.

Lotul de pacienţi cu tensiune sistolică izolată se caracterizează prin corelaţie directă a TAS cu presiunea pulsului, indicele de hipertonie şi suprasarcina de presiune, ceea ce evidenţiază că la valori mari ale TAS cresc în proporţie de 76% presiunea pulsului, PTE 78% şi valorile load în procent de 96%.

Comparaţia dintre TAS cu indexul diurn relevă o corelare indirectă (r=-0,36).

HIPERTENSIUNEA DE HALAT ALB

7 pacienţi (4,3%) din cei 129 investigaţi au prezentat valori tensionale crescute la cabinet, care în decursul monitorizării nu s-au confirmat.

Acest lot se caracterizează prin:

- un număr de 5 femei (3,1%) şi 2 bărbaţi (1,2%), fără a prezenta diferenţe semnificative pe sexe între valorile medii tensionale pe parcursul monitorizării;
- pacienţii cu vârsta sub 65 ani în 4 cazuri (2,5%) şi 2 cazuri peste 65 ani (1,2%).
- corelaţiile TAS cu presiunea pulsului a fost directă (r=0,63), cu suprasarcina de

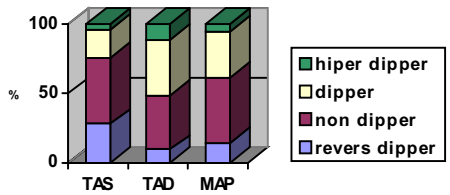

Fig. 4. Indexul diurn în funcţie de tensiunea arterială

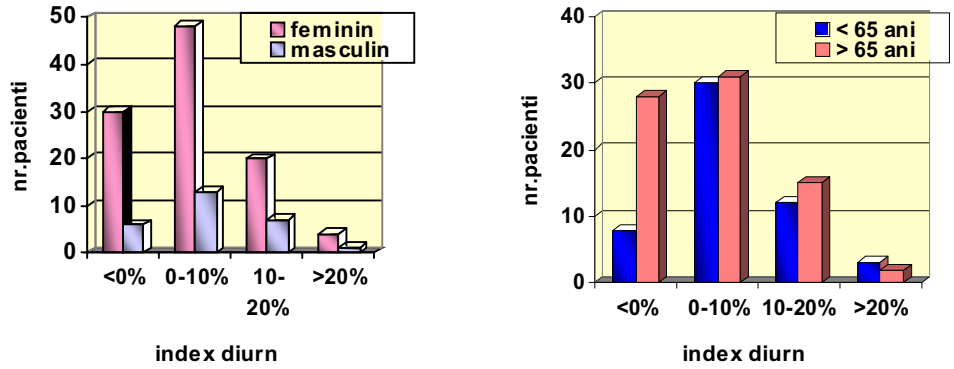

Fig. 5. Indexul diurn în funcţie de sex şi grupa de vârstă PTE

TABELUL IV

Valori medii ale PTE la pacienţii cu tensiune sistolică izolată

Parametru	$\bar{x} \pm \sigma$	Semnificaţie statistică
Sex		
Feminin (n=102)	49,64± 20,02	t = 1,00
Masculin (n=27)	55,58 ± 29,15	p>0,05
Grupa de vârstă		
≤ 65 ani (n=53)	51,38 ± 28,60	t = 0,16
> 65 ani (n=76)	50,53 ± 29,52	p>0,05

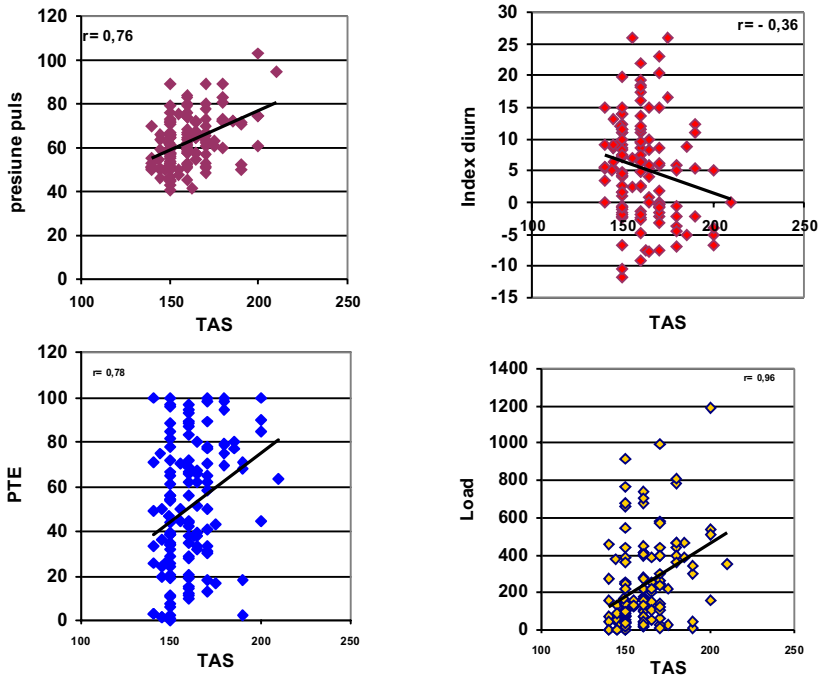

Fig. 6. Corelaţii la lotul cu TAS izolată

presiune (r= -0,41) şi load (r= -0,54) au fost indirecte, iar în comparaţia TAS cu indexul diurn valorile sunt independente (r=0,15).

PARTICULARITĂŢI TERAPEUTICE ALE LOTULUI

Dintre cei 129 de pacienţi, doar 13.7% nu urmau o schemă terapeutică medicamentoasă la intrarea în studiu. Dintre cei 86,3% (111 pacienţi) cu tratament medicamentos, 11,8% (15 pacienţi) urmau monoterapie, 25,4% (33 de pacienţi) urmau tratament cu 2 medicamente antihipertensive, 30,5% (40 de pacienţi) urmau triplă terapie şi 18,7% (24 pacienţi) urmau chiar asocierea a 4 medicamente antihipertensive.

Din întreg lotul, 50 de pacienţi (38,8%) au fost remonitorizaţi la un interval de 6 luni. În această perioadă pacienţii au urmat tratamentul indicat de medic în urma stabilirii diagnosticului. Schemele terapeutice urmate de pacienţii reevaluaţi au fost în principal alcătuite prin asocierea a două (48% dintre cazurile reinvestigate) sau trei medicamente (36%). La 8 pacienţi (16%) s-a practicat monoterapie.

Pe cazuistica studiată se observă că predomină inhibitorii enzimei de conversie a angiotensiunii (ACE-I) în proporţie de 88% dintre cazuri, diureticele tiazidice la 60% dintre pacienţi şi 40% dintre cazuri primesc betablocante.

Ca unic tratament: 12% dintre cazuri au primit numai ACE-I şi 4% betablocante (BB). Cele mai frecvent 2 medicamente asociate au fost ACE-I cu diuretic tiazidic (24%), dar şi ACE-I cu BB (20%). La bolnavii cu infarct miocardic sau insuficienţă cardiacă s-au asociat 3 medicamente, schemele cele mai frecvent utilizate au fost blocantele canalelor de calciu (CCB) + diuretic + ACE-I (16% dintre pacienţii remonitorizaţi) şi ACE-I + diuretic + BB (16%).

Pacienţii au prezentat la 6 luni valori ale tensiunii arteriale sistolice semnificativ mai mici decât la prima investigaţie ($p<0,001$), însă tensiunea arterială diastolică, chiar dacă a prezentat valori medii mai scăzute la remonitorizare, acestea nu au fost semnificative mai mici din punct de vedere statistic ($p>0,05$)

Presiunea pulsului a scăzut semnificativ de la o valoare medie de 89 mmHg la aproximativ 67 mmHg ($p<0,001$).

Indexul diurn, monitorizat Holter 24 de ore a înregistrat valori medii semnificativ mai mari la remonitorizare ($p<0,001$), trecând uşor pragul de 10%.

Monitorizarea Holter evidenţiază, de asemenea, valori medii PTE şi load semnificativ mai reduse la 6 luni ($p<0,001$).

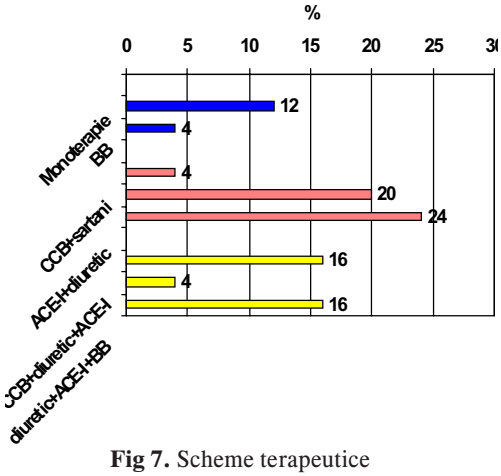

Fig 7. Scheme terapeutice

DISCUŢII

Valorile tensiunii arteriale măsurată la cabinet sunt mai mari decât mediile sistolice şi diastolice măsurate prin monitorizare

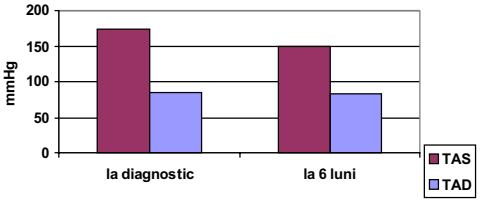

Fig. 8. Valori medii ale tensiunii arteriale la pacienţii cu tensiune sistolică izolată remonitorizaţi

continuă (MCTA), valorile normale pentru fiecare metodă de măsurare fiind precizate de noul Ghid European de Hipertensiune din anul 2007. De aceea O'Brien recomandă MCTA anual la toată populaţia hipertensivă, pentru că reflectă mai fidel valorile tensionale în condiţiile vieţii cotidiene a pacienţilor şi este singura modalitate de apreciere a profilului tensional (4).

Pe grupe de vârstă se observă creşterea TAS şi scăderea TAD odată cu înaintarea în vârstă, expresie a creşterii stiffnes-ului arterial.

Valorile medii tensionale pe grupe de vârstă nu au înregistrat diferenţe semnificative. Aceasta este o caracteristică a lotului, pe care o explicăm prin variabilitatea înaltă a valorilor TAS la vârstnici.

Presiunea pulsului creşte odată cu vârsta şi se corelează direct cu TAS. Valoarea predictivă ca un pacient cu vârsta peste 65 ani să aibă presiunea pulsului peste 50 mmHg este de 63%, de aceea reprezintă factor de risc independent la vârstnici (6) şi constituie ţintă terapeutică.

Predomină profilul nondipper şi reversedipper mai relevant pentru TAS. De asemenea, grupa de vârstă de peste 65 de ani prezintă profil tensional reversedipper în proporţie semnificativ statistic mai crescută. La pacienţii cu HSI analizarea indexului diurn sistolic este mai relevant decât indexul diurn al presiunii medii dar studii mari cu acest obiectiv urmează a fi efectuate.

Valorile cele mai crescute ale sarcinii de presiune (Load) înregistrează frecvenţe mari la TAS : 67,4%.

HTA de halat alb are prevalenţă scăzută în lotul de studiu (4,3%) faţă de datele din literatură (15-30% (7)). Aceasta se explică prin criteriile de selectare a lotului care au înrolat pacienţi vechi hipertensivi în mare proporţie.

Schemele terapeutice de primă alegere bazate pe doze mici de diuretice tiazidice (SHEP) şi blocanţi de calciu cu acţiune lungă (Syst-EUR) au fost completate de utilizarea largă (88% din cazuri) a ACE-I. Aceasta se explică prin prevalenţa crescută a manifestărilor de insuficienţă cardiacă la această categorie de pacienţi, precum şi prin asociere frecventă a tulburărilor de glicoreglare, în particular a diabetului zaharat.

Remonitorizarea continuă a TA după 6 luni de tratament a relevat reducerea semnificativă statistic a tensiunii arteriale medii sistolice, a presiunii pulsului şi a sarcinii de presiune, dar fără a se obţine control tensional. Indexul diurn a fost ameliorat, cu apropiere netă de valoarea normală.

CONCLUZII

Rezultatele obţinute confirmă datele din literatură conform cărora MCTA reflectă cel mai bine comportamentul valorilor presionale, paternurile hipertensive şi profilurile tensionale. Pentru pacienţii cu HSI analizarea parametrilor presionali sistolici definesc mai fidel riscul cardiovascular comparativ cu parametrii presiunii arteriale medii. În practica clinică beneficiul maxim revine pacientului monitorizat, pentru că schema terapautică urmăreşte pe lângă controlul valorilor tensionale şi normalizarea indexului diurn, a sarcinii hipertensive, a presiunii pulsului şi a frecvenţei cardiace.

NOUTĂŢI

DIAGNOSTICUL PRENATAL ŞI POSTNATAL AL SINDROMULUI DE DELEŢIE 22q11.2

Microdeleţia cromosomului 22q11.2 este cea mai frecventa deleţie întâlnită la om (1 la 4000 până la 1 la 6000 nou născuţi vii). Fenotipul variază de la manifestări severe la indivizi aproape asimptomatici. Manifestările clinice cele mai citate sunt anomaliile conotruncale, hipocalcemia datorată absenţei/hipoplaziei glandelor paratiroide, anomaliile palatine şi deficitele imune secundare hipoplaziei/aplaziei timusului, dar aceste semne şi simptome nu sunt constant întalnite. 93% din cazuri sunt de novo, iar restul sunt moştenite de la unul din părinţi. Autorii au realizat un studiu retrospectiv pe o perioada cuprinsă între ianuarie 1997 şi decembrie 2008 la Timone Children Hospital , Marseille, France. Pacienţii incluşi în studiu au fost cei la care s-au efectuat teste pentru microdeleţie 22q11.2 şi au fost împărţiţi în seria prenatală (169 femei însărcinate) şi seria postnatală (714 cazuri). Prezenţa anomaliilor cardiace fetale a reprezentat principala cauză pentru testarea microdeleţiei cu o rată de detecţie de 5% depinzând de tipul de anomalie. În seria postnatală, prevalenţa defectelor cardiace a fost doar de 49%. Semnele dismorfiei faciale subtile reprezintă cheia diagnosticului la pacienţii care nu au manifestările cardinale ale sindromului. O serie de malformaţii identificabile postnatal (despicătură palatină, malformaţii renale şi de membre, defecte de tub neural sau polihidramnios) au fost asociate cu sindromul deleţiei 22q11.2. Pe baza rezultatelor studiului lor, autorii au propus un algoritm care are rolul de a îmbunătăţi rata detecţiei prenatale a microdeleţiei 22q11.2, dar ţi de a reduce numărul testelor prenatale nejustificate. Primul nivel de investigaţii este reprezentat de echografia fetală şi screeningul aneuploidiilor. În cazul în care se depistează o anomalie conotruncală se caută deleţia 22q11.2. Dacă sunt prezente semne minore (de exemplu anomalii renale, polihidramnios, deficit de creştere, despicătura palatina, polidactilie etc) se verifica ecografic arcul aortic, timusul, lungimea urechii si se face consult genetic cu examinarea părinţilor (întrucât în 7% din cazuri deleţia este moştenită de la unul din părinţi). Semnele ecografice anormale sau prezenta unor anomalii la părinţi impune efectuarea cariotipului fetal şi test pentru microdeleţie 22q11.2. Daca însă echografia (arcul aortic, timusul, lungimea urechii) şi consultul genetic la părinţi sunt normale, nu se impune căutarea microdeleţiei 22q11.2 pe proba fetală. Concluziile studiului au fost că se impune testarea prenatală pentru deleţie 22q11.2 în toate cazurile de depistare a anomaliilor conotruncale la făt, iar examinarea arcului aortic şi evaluarea timică trebuie să se facă echografic. Consultul genetic al părinţilor este necesar înainte de testarea fătului pentru deleţia amintită (Bretelle F et al. Prenatal and postnatal diagnosis of 22q11.2 deletion syndrome. *Eur J Med Gen* 2010, doi : 10.1016/j.ejmg. 2010.07.008).

COMPARISON OF DIFFERENT CLASSIFICATION SYSTEMS IN PREDICTING THE OUTCOME OF DIABETIC FOOT ULCERS - RESULTS OF AN OBSERVATIONAL STUDY (Abstract) **Aim**: To compare three ulcer classification systems as predictors of the outcome of diabetic foot ulcers: University of Texas, PEDIS (perfusion, extent/size, depth/ tissue loss, infection, sensation) and IDSA (Infectious Diseases Society of America) infection grading system. **Material and methods**: Ulcer area, depth, appearance, infection and associated ischemia and neuropathy were recorded in a consecutive series of 150 subjects hospitalized with foot ulcer between January 2014 and June 2016. Presence of osteolysis was assessed by foot X-ray. **Results**: Mean age of the study patients was 60.67 years; 101 (68.2%) were male. Most ulcers (75.7%) were treated conservatively, while 36 (24.3%) subjects underwent amputation. Significant differences between patients with amputation and those conservatively treated were observed with regard to depth ($p<0.001$) and extent of lesions ($p<0.001$) using the PEDIS system, Texas grade ($p=0.005$) and IDSA infection severity ($p<0.001$). All three classification systems predicted ulcer outcome ($p<0.001$). No differences were found between these three classifications in terms of predicting amputations in our study group: PEDIS–ISDA ($p=0.53$), PEDIS–TEXAS ($p=0.78$) IDSA–TEXAS ($p=0.62$). **Conclusions:** All three systems predicted ulcer outcome, without obvious benefits of using a particular classification. **Keywords:** DIABETIC FOOT ULCER, AMPUTATION, OBSERVATIONAL STUDY.

The International Federation of Diabetes estimated in 2007 that one-third of the costs for people with diabetes were caused by foot ulcer. The cost of care for patients with diabetes and foot ulcers is 5.4 times higher than for people with diabetes without foot ulcer. The cost of treatment for diabetics with severe ulcers was eight times higher compared to treatment of superficial ulcers (1).

Neuropathy, angiopathy and immunopathy are the key components responsible for diabetic foot ulcer complications (2). Diabetic foot represents a global term for a number of conditions which have in common the same outcome: infection, ulceration, destruction of deep tissue, osteopenia, peripheral vascular disease and neurological anomalies (3). These factors can cause recurrent injuries of all anatomical components of the lower limb: skin, nails, adipose tissue, muscles, fascia, vessels, nerves, bones and joints (4). The occurrence of the risk factors for the

progression of diabetic foot ulcer depends on the metabolic control (5).

History of foot ulcers increases mortality among individuals with diabetes. A ten-year follow-up of the Nord-Trøndelag Health Study, Norway revealed that having a history of foot ulcer was associated with more than a twofold hazard risk for mortality compared with that of the non-diabetic group (6).

Clinical classification systems of diabetic foot aimed to predict the need of foot amputation. A comparison of these systems is important for clinical practice. The aim of this study is to compare the predictive value of three wide used classification systems of diabetic foot ulcers: The University of Texas Wound Classification, The PEDIS Classification (perfusion, extent/size, depth/tissue loss, infection, sensation) and The IDSA (Infectious Diseases Society of America infection grading system).

MATERIAL AND METHODS

We conducted a cross-sectional study during 2014-2016 on a sample of 148 consecutive hospitalized patients for foot ulcers. We collected information on:

- Demographic data: age, gender, area of residence (urban or rural), and level of education;
- The duration of the disease, the presence of chronic complications of diabetes, the type of treatment: insulin or non-insulin agents;
- Laboratory findings: glycated hemoglobin (Hb A_1c), inflammatory parameters (erythrocyte sedimentation rate - ESR, fibrinogen, white blood cells);
- Presence of foot osteolysis on X-Ray.

The University of Texas classification uses four grades (I-Preulcerative or post ulcerative lesion completely epithelialized, II- Superficial wound, not involving tendon, capsule or bone, III-Wound penetrating to tendon or capsule, IV-Wound penetrating to bone or joint), each of which is modified by the presence of infection (Stage B), ischemia (Stage C), or both (Stage D). This system has been validated and is generally predictive of outcome, since increasing grade and stage of wounds are less likely to heal without revascularization or amputation (7).

PEDIS classification was used to evaluate clinical characteristics of foot ulcer: extent, depth, infection, and perfusion. Perfusion was assessed during physical examination (absence of dorsal pedal or posterior tibial artery pulses of the involved foot) and also by performing non-invasive vascular studies: the ankle-brachial index (ABI). Extent was estimated by evaluating the surface of wound. Depth was evaluated using a sterile blunt nasal probe. The diagnosis of infection was based on the presence or absence of symptoms and signs of inflammation, presence of secretion, the results of laboratory tests. Sensation was evaluated with a 10-g monofilament and/or a 128-Hz tuning fork on one or more sites of the foot (8).

IDSA classification (Infectious Diseases Society of America Diabetic Foot Classifications of Diabetic Foot Infection) has been prospectively validated as predicting the need for hospitalization (3).

Statistical analysis was done with *SPSS* software (Statistical Package for Social Sciences) version 13.0 for Windows (Chicago, IL, USA). To assess the association between variables, Spearman correlation coefficients were determined. Wilcoxon test (data were not normally distributed) was used to calculate if there were significant differences between the values of measurements. Chi-square test was used in order to evaluate the significant difference between two or more samples formed from the frequency data. ROC curve assessed the overall ability of the predictor to discriminate between those individuals with the disease and those without the disease. Comparison between the areas under the curve (AUC) resulted from the analysis of

these three classification systems was realized in MedCalc software.

RESULTS

The studied sample included 148 patients (68.2% male) with diabetic foot ulcer. The mean age was 60.77±12.08 years and the duration of diabetes of 12.05±8.75 years. Almost all patients were previously treated with insulin (81.1%). The average HbA1c was 9.71±1.86. An important proportion of patients (27.8%) had osteolysis on X ray exam. A number of 36 diabetics (24.3%) were transferred to surgery for amputation. The prevalence of complications was the following: diabetic nephropathy 47.3%, neuropathy 77.7%, retinopathy 64.7%, peripheral vascular disease 36.9%.

Patients who suffered amputation were older compared with those with conservative treatment (64.17 *vs.* 59.68 years old, p= 0.027). There wasn't a significant difference related to duration of diabetes (10.83 vs. 12.52 years), gender (68.2% males) or the area of residence (50.7% from rural areas). Retinopathy was more frequent among the patients who were amputated (34.6% of patients with diabetic retinopathy (DR) vs. 18.9% of those without DR, p=0.035). The prevalence of other chronic complications was not associated with the prevalence of amputation in the studied sample. Glycated hemoglobin (Hb A_{1c}) had a higher value in surgically treated patients (9.53±1.84 vs.10.58±1.74, p=0.035).

According to the Texas foot ulcers classification, infection was more frequent than ischemia (67.3% vs. 5.4%) and most patients had preulcerative or superficial wounds (39.5%). According to IDSA classification system most patients had moderate infection (tab. I).

TEXAS classification system was highly associated with the necessity of foot amputation (χ = 23.812, p=0.005) (tab. II).

Severity of infection according to ISDA was associated with limb amputations (χ = 23.087, p < 0.001) (tab. III).

The prevalence of amputation increases with the grade of ulcer extent and depth assessed by PEDIS classification (tab. IV).

All three classifications had enough sensibility to predict foot amputation. Wound penetrating to tendon or capsule or those penetrating to bone or joint with moderate or severe infection, which means deep or extensive lesions associated with ischemia or neuropathy had a prediction value for limb amputation (tab. V).

No significant difference was found with regard to the predictive value of the diabetic foot classification systems (tab. VI).

DISCUSSION

In our study the prevalence of amputations for foot ulcers was 24.6%. A meta-analysis conducted by Pengzi Z (9) found a global diabetic foot ulcer prevalence of 6.3% (95% CI: 5.4-7.3%), which was higher in type 2 diabetic patients (6.4%, 95% CI: 4.6-8.1%). The highest prevalence was recorded in North America (13.0%, 95% CI: 10.0-15.9%), while the prevalence in Europe was 5.1% (95% CI: 4.1-6.0%). The higher prevalence of foot ulcers in the diabetics in our study group is possibly explained by the fact that the study was conducted in a facility specialized in foot care.

It was shown that limb ischemia, osteomyelitis, presence of gangrene and ulcer depth were major independent predictors of overall and major amputations. The relationship between major amputation rate and the presence of limb ischemia was very strong. A high Wagner grade was another strong predictor of ulcer outcome. A large observational study conducted by Yesil (10) had shown that several other baseline clinical characteristics such as older age, presence of coronary artery disease. Smoking and ulcer size were associated with either overall or major amputations (11).

Infection was associated with amputation in our patients according to the Texas and ISDA diabetic foot ulcer classifications. Previous studies also showed that limb ischemia and osteomyelitis are associated with an increased risk for amputation (12, 13). Uysal *et al.* (14) found that limb diabetic foot infection and the ulcer duration over 60 days increased the risk for amputation. In patients with diabetic foot, auxiliary methods such as negative pressure contribute in the preservation of the affected limb, after minimal excision (15).

In our study we didn't notice any difference between the type of foot classification in predicting amputation. A study of five classification systems of diabetic foot ulcers (diabetic ulcer severity score (DUSS); University of Texas (UT) diabetic wound classification; Meggitt-Wagner classification; depth of the ulcer, extent of bacterial colonization, phase of ulcer and association etiology (DEPA) scoring system; and site, ischemia, neuropathy, bacterial infection and depth (SINBAD) score) revealed that all five classification systems exhibited high sensitivity, specificity and classification accuracy (16). The Wagner and University of Texas classifications are relatively simple to use to predict the risk for foot amputation. Similar results as those reported by us were found in a prospective study (17). Healing times were not significantly different for each grade of the Wagner or University of Texas systems. There was a significant stepwise increase in healing time with each stage of the UT system, and stage predicted healing similar to that observed in our study patients. In one study, IDSA classification was also associated with limb amputation (3% for no infection, 3% for mild, 46% for moderate and 70% for severe infection) (3).

CONCLUSIONS

In this sample, there weren't notice any difference between the three systems of diabetic foot ulcer classification in predicting amputation. We emphasize that clinical assessment of foot ulcers is important in selecting patients for conservative or for surgical treatment, no matter of the classification system used.

MALONYL DIALDEHYDE IN ISOPROTERENOL-INDUCED ACUTE MYOCARDIAL INFARCTION (Abstract): The **aim** of this study was to determine the correlation between serum and tissue levels of malonyl dialdehyde (MDA) in experimental myocardial infarction and the assessment of MDA potential in the disease early diagnosis. **Material and methods**: Forty rats were divided into five groups: intact (L1=11), 0.9% NaCl control (L2=11), with experimental acute myocardial infarction (L3=6, L4=6, L5=6) induced by subcutaneous injection of Isoproterenol hydrochloride solution 100 mg/kg and sacrificed at 6 hours, 24 hours and 7 days, respectively. Statistical analysis was performed using the Kruskal-Wallis non-parametric test. The results were expressed as median and interquartile range and the Spearman correlation coefficient was calculated (*SPSS 23.0*). **Results:** Serum MDA levels have shown a steady increase in the experimental groups compared to the intact and control ones. In homogenate, MDA presented a significant decrease in L4, with a return in L5 to in the intact and control groups' levels. **Conclusions**: Our study reveals a high level of reactive oxygen species, thus certifying their role in enhancing lipid peroxidation in ischemia, leading to the formation and accumulation of secondary compounds. The presence and expression of MDA is directly dependent on the degree and extent of oxidative stress and reflects the severity of cardiomyocyte membrane lesions with the loss of heart structural integrity in the reported pathology. **Keywords**: MALONIL DIALDEHYDE, OXIDATIVE STRESS, LIPID PEROXIDATION, ACUTE MYOCARDIAL INFARCTION.

By their severity and spread, cardiovascular diseases (CVDs) have reached epidemic proportions, and human and economic losses are steadily increasing. Identification of the factors that cause or predispose to their occurrence has been and remains the goal of many scientific papers in this field (1, 2, 3).

Ischemic heart disease (IHD), and particularly acute myocardial infarction ranks first according to the number of deaths. Myocardial infarction is usually caused by thrombi in the coronary arteries, which block the blood flow and lead to ischemic myocardial necrosis (3). The key role in the occurrence and development of tissue lesions is played by oxidative stress (OS), induced by myocardial ischemia and accompanied by increased production of the reactive oxygen species (ROS), that can damage DNA (Deoxyribonucleic acid), proteins, carbohydrates, lipids and biologi-

cal macromolecules (4). ROS cause both cellular dysfunction, necrosis and/or apoptosis and specific posttranslational modifications, consisting in dysfunction of cellular proteins and myocardial signaling pathways (5). Lipid peroxidation is a sequence of chain reactions mediated by free radicals, that cause oxidative damage to polyunsaturated lipids (6). The products of lipid peroxidation, the unsaturated aldehydes (including MDA), exert toxic effects, determined by their reactivity with nucleophilic compounds and the formation of DNA (with deoxy guanosine, deoxyadenosine and deoxycytidine) and protein adducts (6). MDA-DNA adducts are biomarkers of endogenous DNA damage, thereby the accurate measurement of plasma MDA levels has a strong prognostic significance of oxidative stress (8). MDA has a pronounced atherogenic potential. Interaction of MDA with lysine radicals generates Lyz-Lyz crosslinks, identified in apoB of oxidized LDL (oxLDL) (5). The formation of DAM-collagen crosslinks contributes to cardiovascular tissue stiffness (6). Increased levels of MDA in acute myocardial infarction (AMI) may cause peroxidative damage of the platelets, followed by their aggregation (9).

Recent studies suggest that MDA could serve as a biomarker for both OS (9) and cell membrane injury (6). The data in the literature on the dynamic changes of MDA in serum and homogenate in myocardial ischemia reviewed by us, are insufficient and often contradictory. There are no edifying studies on a biunivocal relationship between serum and tissue MDA levels in AMI. The above-mentioned shortcomings created the premises for the present study, the results of which probably will find answers to some little studied problems, raised by the daily clinical practice.

The aim of our research was to assay the serum and tissue MDA level in experimental myocardial infarction and to assess the potential role in AMI early diagnosis and prognosis.

MATERIAL AND METHODS

An experimental study was performed on 40 healthy white male rats (*Ratta albicans*) weighing 180-230 grams. Animals were kept at the "Nicolae Testemitanu" State University of Medicine and Pharmacy in standard vivarium conditions: temperature 24±2°C, 12-hours day/night cycle, free access to adequate food and water. Manipulations were carried out at the Laboratory of Biochemistry of the "Nicolae Testemitanu" State University of Medicine and Pharmacy. The study protocol was approved by the Research Ethics Committee of the above-mentioned university (23.03.2015).

AMI was induced by a single subcutaneous injection of 100 mg/kg Isoproterenol hydrochloride (*Sigma Aldrich Chemie GmbH*) dissolved in physiological solution. According to the study design, the animals were randomly divided into 5 groups: intact (L1 = 11) animals kept in standard vivarium conditions; control (L2 = 11) animals to which the physiological solution was administered subcutaneously; experimental (L3 = 6; L4 = 6; L5 = 6) animals receiving 100 mg/kg isoproterenol hydrochloride subcutaneously and sacrificed under sterile conditions and sulfuric ether anesthesia after 6 hours (AMI 6h), 24 hours (AMI 24h) and 7 days (AMI 7d).

Apical cardiac tissue (300mg) was homogenized in ice with 3 mL of 0.25M sucrose buffer (pH 7.4). The obtained homogenate was treated with 30 μL of Triton X-100, placed in the refrigerator for 30

minutes, and centrifuged at 4°C at 3,000 rpm for 10 minutes. The supernatant was stored at -40°C.The collected blood samples were centrifuged for 10 minutes at 1500 rpm. Serum was collected in Eppendorf tubes and kept at -40°C. MDA levels in the biological samples were assessed according to the method modified by Gudumac V *et al.* (10). The MDA content was expressed in µM/L (serum) and µM/g*protein (tissue).

Statistical analysis

The obtained data were statistically processed using the software *SPSS 23.0* version. The descriptive statistics methods were used for median and interquartile range (IQR) calculation. The data distribution was analyzed using the *Kolmogorov-Smirnov* and *Shapiro-Wilk* normality tests.

The homogeneity of variances was evaluated by the *Levene* test. Groups were compared using *Kruskal-Wallis* nonparametric test. The correlation coefficient was calculated by the *Spearman* correlation test. Statistically significant was considered the p value less than 0.05.

RESULTS

In *homogenate MDA values* registered statistically significant variations, initially expressed by slight increase from 4.47 µM/g*protein, IQR 0.78 in intact rats to 4.60 µM/g*protein, IQR 0.78 in AMI6h group, followed by decrease to 3.60 µM/g*protein, IQR 0.47 in AMI24h group (p = 0.002), and return to baseline values of 4.50 µM/g*protein, IQR 0.38 in AMI7d group (p = 0.004) (fig. 1).

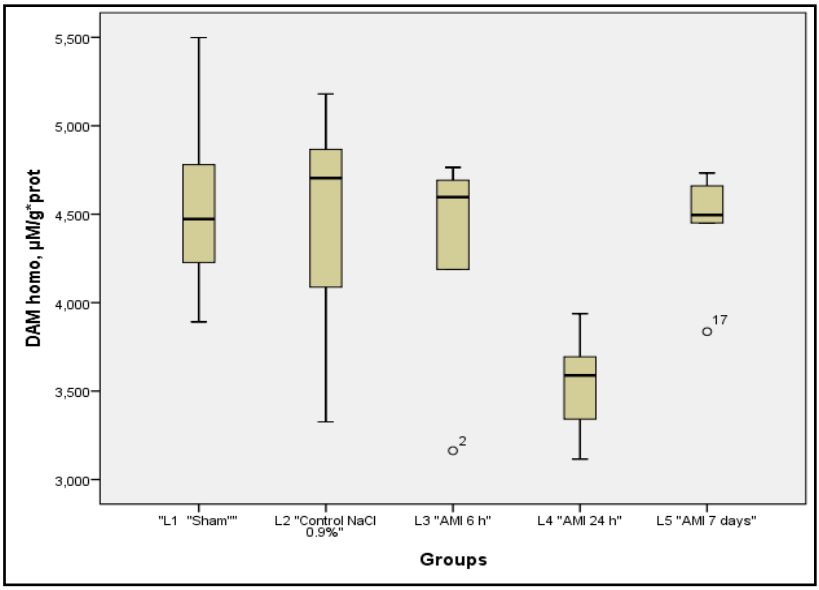

Fig. 1. MDA variations in homogenate

The *modifications of serum* MDA levels were statistically insignificant (fig. 2), with an increase from 19.08 µM/L, IQR 4.76 assessed in the intact group to 20.07 µM/L, IQR 4.02 in the AMI6h group, and to 20.57 µM/L, IQR 5.26 in AMI7d group (p>0.05).

No correlations were found between the serum and homogenate MDA levels.

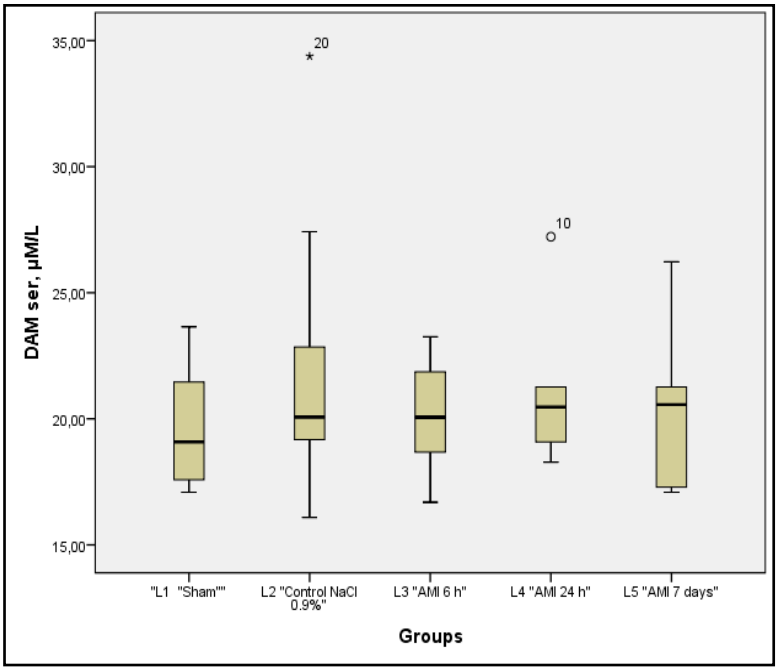

Fig. 2. Serum MDA levels

DISCUSSION

Functional cells permanently generate free radical and reactive oxygen species as part of metabolic processes, the overproduction of which can result in oxidative stress (6). Free radicals are unstable molecules that tend to interact with cell structures (8). ROS can damage fundamental cell biomolecules, including DNA, proteins and lipids (7).

The mechanisms mediated by both free radicals and lipid peroxidation are at the basis of cardiovascular diseases (6). Lipid peroxidation is a chain reaction that accompanies oxidative stress, induces the formation of various active compounds, and results in damage of cell activity (8). The assessment of lipid peroxidation in tissues is a relevant marker to establish the extent of oxidative stress (6). Lipid peroxides derived from polyunsaturated fatty acids are unstable, and quickly break down to secondary compounds (8), that can accumulate at low oxygen pressure in tissue during ischemia (9). MDA is the most commonly known by-product of lipid peroxidation, which can serve as a reliable biomarker of oxidative stress (8), cell membrane injury and indicator of cell and tissue oxidative damage (6).

In our study, MDA content in homogenate initially showed a 3% increase in AMI6h, followed by a 20% decrease in AMI24h, and return to baseline values in AMI7d, that disagrees with the data presented by Kathyaini R. *et al.* (9) in 2017. Possibly the MDA level generated in the cardiac tissue in AMI, characterizes the presence of hypoxic lesions, but it is fast removed from tissue in 24 hours at the same time with the worsening of membrane damage and loss of its integrity. The results reported by Rasool et al. (4) indicate a

significantly higher MDA level in patients with cardiovascular diseases. Singh et al. (8) have experimentally demonstrated that ischemia/ reperfusion induces myocardial formation of MDA: small but detectable amounts are accumulated during ischemia, while marked increase occurs during reperfusion. Studies by Jena et al. (11) and Behera et al. (12) proved the significant increase of serum MDA levels in ischemia. Bastani A. et al. (7) have mentioned the significant elevation of MDA in acute coronary syndrome. The discrepancy in the established MDA content is also the result of both the duration and degree of ischemia in various studies.

Our results are within the ranges reported in the literature and show a 5% increase of *serum MDA* in AMI6h, as well as in AMI24h and AMI7d, exceeding the intact group´s level by 7% and 8%, respectively. The data reported by us confirm that myocardial ischemia is associated with increased generation of ROS, induces oxidative stress and intensifies the lipid peroxidation process, which initially reveals the development of ischemic changes followed by loss of membrane integrity, subsequently leading to necrotic lesions. MDA elevation in AMI indicates an imbalance between oxidative and protective mechanisms, which results in the development of oxidative stress in AMI patients (13).

Significantly elevated MDA levels correspond to the early stage of oxidative stress (6) and confirm the presence of ROS-induced cardiomyocyte membrane lesions (9). Changes that are regularly detected with a certain reproducibility demonstrate an increased sensitivity and specificity with significant potential for AMI identification and prognosis.

CONCLUSIONS

The results of our research reveals a high ROS content, thus certifying their role in exacerbation of lipid peroxidation in ischemia, with the formation and accumulation of secondary compounds. The presence and expression of MDA is directly related with the degree and extent of oxidative stress and reflects the severity of cardiomyocyte membrane changes with loss of heart structural integrity AMI.

NEWS

EFFICACY OF PIRFENIDONE IN THE CONTEXT OF MULTIPLE DISEASE PROGRESSION EVENTS IN PATIENTS WITH IDIOPATHIC PULMONARY FIBROSIS

Declines in percent predicted FVC (% predicted FVC), declines in 6-min walk distance (6MWD), and respiratory hospitalizations are events associated with disease progression and mortality in idiopathic pulmonary fibrosis. The incidence of multiple events in the same patient over 12 months of pirfenidone treatment is unknown. Patients who received pirfenidone 2,403 mg/d (n = 623) or placebo (n = 624) in the ASCEND (study 016; NCT01366209) and CAPACITY (studies 004 and 006; NCT00287716 and NCT00287729) phase III trials were included in this post hoc analysis. Disease progression events were defined as relative decline in % predicted FVC $\geq$ 10%, absolute decline in 6MWD $\geq$ 50 m, respiratory hospitalization, or death from any cause. The incidence of disease progression events over 12 months was assessed. The most frequent disease progression events were declines in % predicted FVC (pirfenidone vs placebo; 202 *vs.* 304 events) and declines in 6MWD (pirfenidone vs placebo; 265 *vs.* 348 events). Fewer patients who received pirfenidone had more than one progression event compared with placebo (17.0% *vs.* 30.1%; $p < .0001$). Death following one or more progression event occurred less frequently in the pirfenidone group than in the placebo group (2.1% *vs*. 6.3%; $p = .0002$). Pirfenidone significantly reduced the incidence of multiple progression events and death after a progression event over 12 months of treatment compared with placebo. These findings suggest that continued treatment with pirfenidone confers a benefit despite the occurrence of any single disease progression event. (Steven D. Nathan, Ulrich Costabel, Ian Glaspole, Marilyn K. Glassberg, *et al. CHEST* 2019; 155(4): 712-719).

BIOCHEMICAL PARAMETERS IN HEPATITIS C VIRUS INFECTION IN CHILDREN

BIOCHEMICAL PARAMETERS IN HEPATITIS C VIRUS INFECTION IN CHILDREN (Abstract): Hepatitis C can lead to liver fibrosis. **Aim:** In this study, we evaluated the age, gender, body mass index (BMI), route of transmission and biochemical parameters of children treated with Interferon vs Interferon + Ribavirin and the relationship with fatty liver disease (FLD) and response to treatment. **Material and methods:** This retrospective and prospective study was conducted over an 8-year period (2009-2017) and included 62 children, aged 6-18 years, diagnosed with hepatitis C, admitted to 2nd Clinic of Pediatrics of "Sf. Maria" Children's Emergency Hospital, Iasi. The patients studied were divided into 2 groups: group I - 28 patients who received monotherapy (Interferon) and group 2 - 34 patients who received combination therapy (Interferon + Ribavirin). Liver fibrosis was assessed using FibroScan, and the presence of FLD by abdominal ultrasound. Biochemical parameters were determined at the initiation and at the end of antiviral therapy, 48 weeks. **Results:** In both groups, vertical transmission was the most common route of hepatitis C virus (HCV) infection, but in a large proportion of patients the transmission route could not be identified. The biochemical parameters aspartate aminotransferase (AST), alanine aminotransferase (ALT), gamma-glutamyl transpeptidase (GGT) were elevated in both group at the initiation of treatment, but decreased during treatment, and the relationship between aminotransferases and FLD was also demonstrated. HCV RNA levels showed a positive correlation with ALT in both study groups (p=.002 in group 1 and p=.036 in group 2). We have also found a negative association of HCV-RNA with bilirubin (r=-.148, p=.000) in group 1. **Conclusions:** The relationship between biochemical parameters and FLD may be a marker of hepatitis progression and of prognosis in these patients. **Keywords:** HEPATITIS C, INTERFERON, RIBAVIRIN, BIOCHEMICAL PARAMETERS.

Hepatitis C virus (HCV) was discovered more than twenty-five years ago (in 1989), but only in recent years the infection caused by this virus has been recognized as a public health problem. Approximately 3% of the world population (180 millions) is infected with HCV (1). Because of the asymptomatic interval of over 2-3 decades, 75% of those infected with HCV are not diagnosed until late, when complications

such as cirrhosis or hepatocellular carcinoma (HCC) are difficult to treat. Between 1996 and 2006, the prevalence of cirrhosis doubled and that of HCC increased twenty times (2).

Hepatitis C virus is an RNA virus that belongs to the family *Flaviviridae*. HCV replicates in the cytoplasm of hepatocytes but is not directly cytopathic. Persistent infection appears to rely on rapid production of virus and continuous cell-to-cell spread, along with a lack of vigorous T-cell immune response to HCV antigens. The HCV turnover rate can be quite high with replication ranging between 1010 to 1012 virions per day, and a predicted viral half-life of 2 to 3 hours. The rapid viral replication and lack of error proofreading by the viral RNA polymerase are reasons why the HCV RNA genome mutates frequently. There are six known genotypes and more than 50 subtypes (3).

High genetic variability of HCV makes it possible to successively infect the host with several viral strains, this being in direct correlation with the severity of disease, the response to antiviral therapy and difficulties in the preparation of effective vaccines.

Children with HCV infection differ from adults in several ways including clearance rate, mode of transmission, progression of fibrosis and duration of potential chronic infection when acquired at birth (4).

In adults in developed countries, the most important route of HCV transmission is intravenous drug use, whereas in resource poor countries, invasive procedures or injection-based therapies with contaminated instruments are the predominant source of new infections (5).

But in children things are different. Vertical transmission of HCV infection is the most common route. In the United States 7,500 new cases are reported each year. In the last decade it is more common in HCV-positive mothers, the risk being 5%, and in HIV/HCV-coinfected mothers the risk increases to 20%. Vertical transmission encompasses several potential transmission routes from an infected woman to her newborn: intrauterine, intrapartum, and postnatal. The pathogenesis of HCV infection during pregnancy is dominated by immunological changes associated with gestation and maternal-fetal tolerance, resulting in increased HCV viral load in the third trimester of pregnancy, which leads to a high risk of HCV transmission to the fetus (5, 6).

Children infected by vertical transmission have a high rate of spontaneous resolution approaching 25-40%. Most of them have spontaneous resolution within the first 2 years, but some of them, 6-12%, may have spontaneous resolution as late as 7 years after infection.

Chronic hepatitis C is associated with a wide variation in serum ALT level, from normal ALT to persistent elevation of ALT. Approximately 25-30% of individuals with chronic HCV infection have persistently normal ALT level (7).

In case of persistent HCV-RNA, the rate of liver fibrosis progression varies widely. There have been extensive studies focusing on the natural course of disease progression from chronic hepatitis C to cirrhosis, HCC, and death. Several studies have shown a significant association between the rate of fibrosis and the age at the time of infection. After determining the estimated duration of HCV infection, the stage of fibrosis was significantly higher in patients infected at an older age (> 40 years

old), than in those infected at younger ages, like children (8).

There have been significant advances in the understanding the virology and natural history of chronic HCV infection in children. In addition, there are now several treatment options for children with chronic HCV infection and many new therapies on the horizon (9).

The aim of this study was to evaluate the age, gender, route of transmission, BMI, response to treatment and identify the biochemical changes in patients with hepatitis C prior to and during antiviral treatment comparing the two groups of patients, group 1 who received Interferon vs group 2 who received Interferon+ Ribavirin, and the relationship with fatty liver disease (FLD).

MATERIAL AND METHODS

We conducted a retrospective and prospective study of 62 children, aged 6-18 years, diagnosed with viral hepatitis C and admitted to the 2nd Clinic of Pediatrics of "Sf. Maria" Children's Emergency Hospital, Iasi, Romania between 2009 and 2017. The study included 2 groups of patients:

- group 1: 28 patients who received monotherapy (Interferon)
- group 2: 34 patients who received combination therapy (Interferon + Ribavirin).

Inclusion criteria were positive diagnosis of hepatitis C and detectable HCV RNA, age over 6 years, liver fibrosis > F2, and parental consent. Informed consent was obtained from the parents, containing permission to do laboratory tests, abdominal ultrasound and FibroScan. The study was approved by the Ethics Committee of the "Sf. Maria" Children's Emergency Hospital Iasi.

Patients who were included in group 1 were selected after the presence of anemia and thyroid dysfunction that contraindicates the administration of Ribavirin and the chronological criterion, meaning that in 2009 the only therapeutic option in children was represented by Interferon in patients with HCV infection.

The biochemical parameters (AST, ALT, GGT, bilirubin, and ALP) and HCV-RNA were also determined at the initiation (AST1, ALT1, GGT1, BILIRUBIN1, ALP1 and HCV-RNA1) and at the end of antiviral therapy, 48 weeks (AST4, ALT4, GGT4, BILIRUBIN4, ALP4 and HCV-RNA4). Liver fibrosis was assessed by FibroScan, and the presence of FLD by abdominal ultrasound.

Viral factors like HCV-RNA were correlated with biochemical parameters such as ALT and bilirubin level, and the ROC curve showed us the predictability of FLD risk.

In the study, the statistical analysis and graphical representations were performed in the *SPSS* program, where correlation coefficient r Pearson, measure degree of connection between variables and p represents a measure of statistical significance.

RESULTS

In group 1, mean age was 11.85 years, and 53.5% were male. The risk factors with the highest frequency among these patients were: vertical transmission (28.5%), blood transfusions (7.14%) and dental treatments (3.57%) (fig. 1). Analyzing the weight of the patients I found that 46.63% of the patients were overweight, with a BMI of 22.58 ± 4.9 kg/m².

According to FibroScan, 92.86% of the patients had a METAVIR score F2 and 7.14% F3. All patients were evaluated by

abdominal ultrasound and 60.71% of them had FLD.

Evaluation of the therapeutic response showed that 64.29% of the patients had sustained virological response (SVR) at 24 weeks after the completion of the antiviral therapy.

In group 2, mean age was 11.5 years, and 61.7 % of the patients were female. The proportion of cases in which we have identified the existence of risk factors for HCV infection was of 58.9%, in 26.4% of them vertical transmission, followed by dental treatment, 11.76%, blood transfusion and surgery in 8.82% of patients, and 2.94% by tattoos (fig. 1). In both study groups the transmission route has not been identified in a significant percentage of patients. In the group 2, 42.94% of the patients were overweight, with a BMI of 23.34 ± 3.2 kg/m² before starting antiviral therapy.

All group 2 patients (100%) had a F2 METAVIR score, and 61.76% presented FLD (tab. I). At 24 weeks after completion of therapy 88.2% of patients had SVR.

F2	26 (92.86%)	34 (100%)	
F3	2 (7.14%)	-	
F4	-	-	
Abdominal ultrasound			
FLD	17 (60.71%	21 (61.76)	

In group 1 mean serum AST and ALT levels at initiation of Interferon therapy were 88.11 UI/mL ±57.25 and 92.35 UI/mL ± 53.40, respectively. Mean bilirubin, ALP and HCV-RNA levels were 1.38±0.70 mg/dL, 453.03 ± 195.76 UI/mL and 1,419,083.89 UI/mL ± 2140692.14, respectively, with a positive correlation between ALT and HCV- RNA (p=.002) and a negative correlation between bilirubin and HCV-RNA (r =.-148, p=.000) (tab. II).

TABLE II

Biochemical parameters

Biochemical markers	Group 1	Group 2
AST1 (UI/mL)	88.11±57.25	91.41 ± 82.40
AST4 (UI/mL)	43.39 ±19.40	39.58±18.08
ALT1 (UI/mL)	92.35±53.40	103.44± 59.60
ALT4 (UI/mL)	40.2 ±21.45	41.35±23.34
GGT1 (U/L)	47.07 U/L ±23.01	46.35±22.81
GGT4 (U/L)	35.01 U/L ±8.40	34.82 U/L±8.60
BILIRUBIN (mg/dL)	1.38±0.70	1.01±0.69
ALP (UI/mL)	453.03±195.76	430.14±19.7
ARN-VHC1 (UI/mL)	1419083.89±2140692.14	1039838.67 ±1796386.77
ARN-VHC4 (UI/mL)	179714.28±341911.46	322640.70±877730.75

At the end of 48 weeks of treatment, mean serum AST and ALT levels were 43.39 UI/ mL ± 19.40 and 40.2 UI/mL ± 21.45, respectively (tab. II). Most of the patients showed normal values at the end of therapy.

Mean serum GGT level at therapy initiation was 47.07 U/L ± 23.01, and at the end of therapy 35.01 U/L ± 8.40.

The ROC curve revealed that ALT (68.7%) and AST (61.7%) show good predictability for FLD in this group of patients (fig. 2, tab. III).

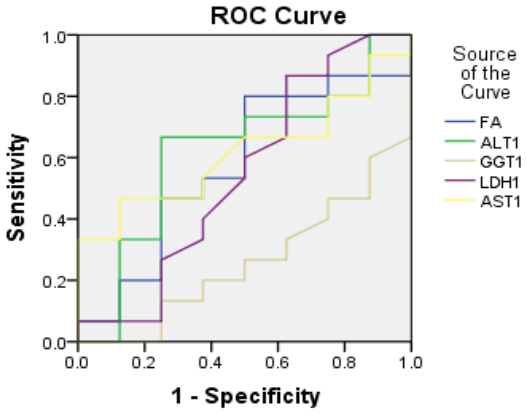

Fig. 2. ROC curve for the predictability of FLD risk

TABLE III
Biochemical markers for the predictability of FLD risk

Test Result Variable(s)	Area
ALP	.575
ALT1	.687
GGT1	.258
LDH1	.546
AST1	.617

In group 2, mean serum AST and ALT levels at initiation of Interferon and Ribavirin therapy were 91.41 UI/mL ± 82.40 and 103.44 UI/mL ± 59.60, respectively (tab. II).

Mean serum bilirubin, ALP and HCV-RNA were 1.01 ± 0.69 mg/dL, 430.14 ± 19.7 UI/mL and 1039838.67 UI/mL ± 1796386.77, respectively, with a positive correlation between ALT and HCV-RNA (p=.036). At the end of the 48 weeks of treatment, mean serum AST and ALT levels were 39.58 UI/mL ± 18.08 and 41.35 UI/mL ± 23.34, respectively (tab. II).

We've found that ALT levels were more elevated in boys than in girls in both study group.

Mean serum GGT level at therapy initiation was 46.35 U/L ±22.81, and at the end of therapy 34.82 U/L ± 8.60.

The ROC curve revealed that ALT (56.6%) and AST (54.9%) show good predictability for FLD in this group of patients (fig. 3, tab. IV). We found that the correlation between HCV-RNA and AST, ALP and GGT was not significant.

Biochemical markers for the predictability of FLD risk

Test Result Variable(s)	Area
AST1	.549
ALT1	.566
GGT1	.396

DISCUSSION

Since the introduction of Interferon for the treatment of hepatitis C, the definition of what constitutes a response to therapy has evolved considerably. Therefore, serum ALT has been used as a surrogate marker of HCV-RNA, and the purpose of antiviral therapy is to achieve both a biochemical

and virological response, especially since AST and ALT are closely related to the occurrence of FLD, which in turn leads to the progression of hepatitis C to cirrhosis (10, 11).

Many patients with chronic hepatitis C have FLD. FLD is defined as excessive lipid accumulation within the hepatocyte cytoplasm and has been more recently recognized as a significant cause for cirrhosis in the United States. There are two forms of FLD in patients with hepatitis C, specifically metabolic statuses and HCV-induced statuses (12). Metabolic statuses is a process which occurs in the setting of obesity, hyperlipidemia, and elevated serum AST and ALT and insulin resistance. The other type of steatosis found in patients with HCV is fatty infiltration that is directly elicited by the virus (13).

This study included 2 groups of patients diagnosed with hepatitis C. Group 1 included 28 children with a male predominance (53.5%), and group 2 included 34 children with female predominance (61.7%). In both study groups, the main transmission route was the vertical one, which means a longer infectious period during which FLD and fibrosis may occur. In our study the primary route of transmission was vertical, in agreement with the findings of other authors (14).

Over 50% of our study patients were also diagnosed with FLD by abdominal ultrasound. Obesity play an important role in the appearance of FLD therefore the BMI is an important variable in the analysis of patients with HCV infection (16). In our study 46.63% of patients in group 1 and 42.94% of patients in group 2 were overweight before beginning antiviral therapy. This may be related to the presence of FLD in the patients we followed. Elevated aminotransferase levels act as an indicators of cell injury. Our study showed a favorable evolution of aminotransferases during antiviral therapy in both groups of patients and we found a positive correlation between ALT with HCV-RNA in both study groups. In a study from India conducted by R. Abraham et al. in 105 patients it was found that serum ALT level correlated poorly with HCV-RNA. Other studies had found correlation between serum ALT and HCV-RNA (17).

Bilirubin and ALP levels were followed, and we found a negative correlation between bilirubin and RNA-HCV in group 1. Elevated bilirubin level is usually associated with liver injury and can be useful to determine the optimal dose of Interferon (18).

Mean AST, ALT and GGT levels at initiation of antiviral therapy were above the upper limit of normal, but their values showed a downward curve in patients treated both with monotherapy and combination therapy.

In both study groups the ROC curve was performed to test the biochemical markers for the predictability of the FLD risk, which revealed that AST and ALT show good predictability, data also reported by other authors (19, 20).

CONCLUSIONS

Our study shows that in patients with HCV infection which are overweight AST and ALT levels during antiviral therapy have a strong relationship with HCV-RNA and FLD, therefore decreased of BMI should be considered in this group of patients. Aminotransferases showed a significant decrease in both study groups during antiviral therapy therefore, the normalization of serum aminotransferases leads to improved prognosis of patients with hepatitis C.

This may lead to the conclusion that these biochemical parameters and BMI may be used as prognostic factors at patients with HCV infection.

ENDO-HISTOLOGICAL CORRELATION IN CHRONIC GASTRITIS BY *HELICOBACTER PYLORI* (Abstract): In this study, we analysed the correlations between endoscopic aspects and histopathological changes at the patients with dispeptic simptoms and anti-Helicobacter pylori antibodies, investigated with upper endoscopy. **Material and methods**: Our study comprised of 418 patients from Bacău Hospital, in period October 2005 - October 2008. Histopathological diagnosis was correlated with endoscopic aspects. **Results**: Average age was 55 years, with predominance of woman and rural people, without statistical significance. Histopathological diagnosis of nonatrophic gastritis was found at 211 (50%) patients, atrophic gastritis at 192 (46%) patients, intestinal metaplasia at 108 (26%), low grad intraepithelial neoplasia at 70 (17%), high grad intraepithelial neoplasia, at 4 (1%) patients, neoplasia at 28 (7%). The most severe diagnostic was atrophic gastritis with intraepithelial neoplasia. Our analysis has found nonatrophic gastritis in 211 patients (50%), atrophic gastritis in 192 (46%), intestinal metaplasia in 108 (26%), low grade intraepithelial neoplasia in 70 (17%), high grade intraepithelial neoplasia in 4 (1%), superficial gastric carcinoma in 27 (7%) and one MALT lymphoma. **Conclusion**: There was no correlation between the endoscopical aspects and the histological diagnosis. All histological changes were strongly related to *Helicobacter pylori* infection. Prospective studies are needed to evaluate whether the eradication of *Helicobacter pylori* will indeed reduce the risk of gastric cancer. **Key words**: GASTRITIS, HELICOBACTER PYLORI, INTESTINAL META-PLASIA, INTRAEPITHELIAL NEOPLASIA

CHRONIC HEPATITIS C VIRUS INFECTION AND PERIPHERAL NEUROPATHY

CHRONIC HEPATITIS C VIRUS INFECTION AND PERIPHERAL NEUROPATHY (Abstract): Hepatitis C virus infection has been associated along time with non-liver manifestations, including cardiovascular, renal, metabolic, immune-related, and central and peripheral nervous system damage. The **aim** of this study was screening for chronic, distal and symmetrical peripheral neuropathy (PN) in a group of patients treated with interferon -free regiments and to determine the influence of sustained viral response (SVR) on the clinical symptomatology. **Material and methods:** The study involved 132 patients, with different stages of liver fibrosis (F1-F2) and (F3-F4) treated with interferon-free regiments, which achieved SVR. We screened patients using clinical examination and neuropathy disability score (NDS) for chronic, distal and symmetrical PN and follow its evolution or remission after SVR. All patients were evaluated in three different moments: at baseline, after achieving SVR and more that 6 months after SVR. **Results:** Out of 132 patients, 36 had been identified with PN, a higher incidence in the subgroup with advanced liver fibrosis was found. After SVR an clinical improvement in PN was seen in both groups of liver fibrosis, more pronounced near complete remission in the F1-F2 fibrosis group. NDS score improved also in > 90 % of patients with early/ significant fibrosis and decreased over time in the F3-F4 group, the results had statistical significance (p = 002*). **Conclusions:** After interferon-free therapy serious improvement is seen in HCV infected population regarding the severity of the polyneuropathy but also in clinical symptomatology. **Keywords:** CHRONIC HEPATITIS C VIRUS INFECTION, PERIPHERAL NEUROPATHY, INTERFERON-FREE REGIMENS.

Hepatitis C virus (HCV) infection is a major health problem affecting about 71 million people all over the world and is a leading cause of cirrhosis and hepatocellular carcinoma (1). On the other hand, there are several reported non - liver HCV- associated disorders, including cardiovascular (ischemic heart disease), renal (glomerulonephritis, renal insufficiency), metabolic (insulin resistance, type 2 diabetes), immune-related (mixed cryoglobulinemia, sicca syndrome, immune thrombocytope-

nia), central and peripheral nervous systems (PNS) (2). HCV infection increases mortality from booth hepatic and extrahepatic diseases (3, 4). Among the neurological extrahepatic manifestations of chronic HCV infection, peripheral neuropathy (PN) is one of the most frequently associated in variable proportions from 10% (5) to 50% (6).

Since the discovery of interferon treatment, researchers studied the long-term effects of sustained virologic response (SVR) on liver disease and non-liver manifestations in order to observe its effect of the all-cause mortality. The conclusion of many studies was that SVR may decrees overall mortality from both causes, either hepatic also extrahepatic manifestations of HCV infection (7, 8).

Combination therapy with interferon pegylated or standard and ribavirin may achieve clinical symptomatology resolution in patients with cryoglobulinemic related polyneuropathies (9, 10). In patients with PN and negative cryoglobulinemic status the influence of SVR is still unclear, although cases of clinical resolution of PN in these patients are cited in the literature (11).

The current treatment of HCV infection with interferon - free regiments is highly effective with rates of SVR more than 95 %, fare tolerance and few side effects (12). It has been expected that such effective treatment will reduce morbidity and mortality of HCV liver related complications as well as extrahepatic manifestations (8). There are several studies which reported improvement in patients with PN associated with cryoglobulinemia after interferon free regiments (13, 14). However, studies regarding use of interferon-free regiments in PN without cryoglobulinemia are lacking.

MATERIAL AND METHODS

This is a prospective observational study of 132 patients with chronic HCV infection who obtained SVR after therapy with based combinations of Paritaprevir / Ombitasvir / Ritonavir and Dasabuvir or Sofosbuvir / Ledipasvir for 12 weeks, between 2015-2019 at Institute of Gastroenterology and Hepatology, Iasi, Romania. All patients were evaluated for inclusion in the antiviral treatment for HCV. All patients included in the study accomplished the criteria for antiviral treatment recommended by the Romanian health protocol. Patients included in this study were screened for polyneuropathy in three different moments: at the baseline, after achieving SVR and after more than six months after SVR. All patients were evaluated according to the protocol and liver fibrosis was assessed by Fibroscan or Fibromax measurements. The study group was divided in patients with early/significant liver fibrosis (F1-F2) and advanced liver fibrosis (F3) and cirrhosis (F4).

Diagnosis for polyneuropathy was established clinically by symptomatology and neuropathy disability score (NDS) (tab. I). Paresthesia was the dominant symptom mainly described as tingling, burning sensation, a feeling of constriction, buzzing or stinging.

Statistical analysis. The statistical analysis was carried out using *SPSS 24.0* software. Continuous data were expressed + SD and categorical data as percentage. We used Mann Whitney U test to compare groups based on the degree of fibrosis, and *Chi square* for categorical variables.

TABLE I

Neuropathy disability score

	Right	Left
Pin prick	0 = present 1 = absent	0 = present 1 = absent
Vibration perception threshold (normal = can distinguish vibrating/non vibrating)	0 = present 1 = absent	0 = present 1 = absent
Temperature perception	0 = present 1 = absent	0 = present 1 = absent
Achillean reflex	0 = present 1 = present with reinforcement 2= absent	0 = present 1 = present with reinforcement 2= absent
Interpretation	0 -1 normal 2 -6 = mild modifications 6 –9 = abnormal scoring with high severity risk for neuropathy ≥ 9 - 10 = complete loss of sensation	

RESULTS

Baseline demographics, clinical and characteristics of the study lot are presented in the second table. In this study we subdivided the patients includes using two groups of fibrosis based on the results of the Fibroscan and Fibromax (tab. III).

Polyneuropathy was found in 36 patients. Polyneuropathy had a higher incidence in the subgroup with advanced liver fibrosis (F3-F4) - 32 patients (29.1%) compared with those with early/significant liver fibrosis (F1-F2)- 4 patients (18.2 %) (fig.1). These finding highlight that not only the presence of the HCV itself is a cause of incident polyneuropathy but also the duration of the chronic disease. We found a clinical regression of the polyneuropathy after achieving SVR from 29.1 % to 23.6% in the advanced fibrosis group (fig.1). We noticed that in this stage of evaluation an improvement of the polyneuropathy is seen in patients with advanced fibrosis and no modification in severity in the early/significant fibrosis group.

TABLE II

Baseline biochemical and demographic characteristics of the study lot

Parameter	HCV group n= 132
Age (yrs.) (mean + SD)	50.90± 19.2
Rural/ Urban area	75/57
Sex (M/F)	47/85
Hemoglobin (g/dL)	11.78±2.21
Platelets (x10^9/mmc) (mean ± SD)	181±17.22
Albumin (g/dL)	2.89±1.22
Age < 65 (yrs.)	67
Age > 65 (yrs.)	51

TABLE III
Subdivided groups based on the stage of liver fibrosis

Stages of fibrosis	Patients (n)	Percent (%)
F1	4	3.0
F2	18	13.6
F3	24	18.2
F4	86	65.2
Total	132	100.0

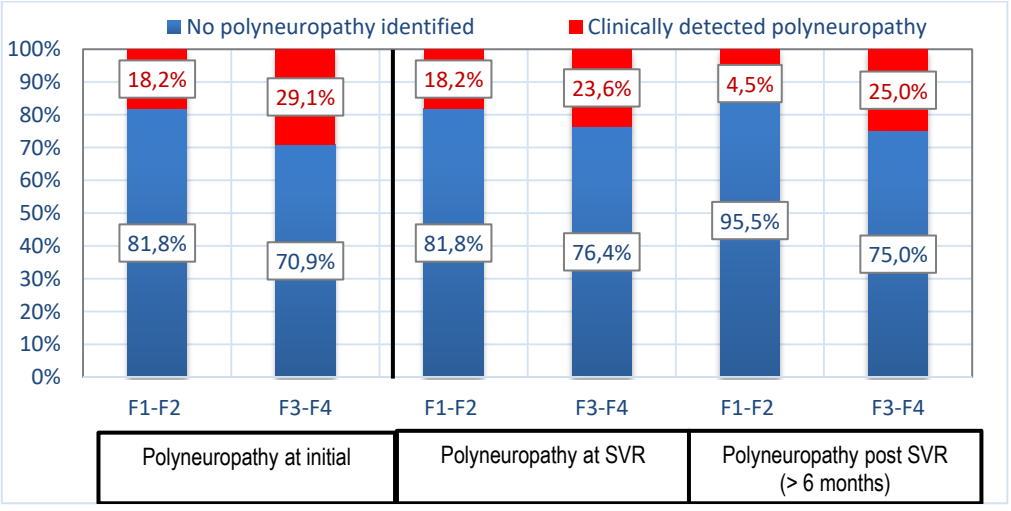

Fig. 1. Incidence of polyneuropathy screened in three study periods

An important finding was seen in the subgroup of patients with F1-F2 fibrosis where out of 4 patients (18.2%) the reduction on the NDS was seen in more than 90% of the cases, still remaining one patient (4.5%) with PN. The difference between these two subgroups had no statistical significance (p= 1.56).

After assessing the incidence in the study lot based on the stages of liver fibrosis, we characterized the evolution in time of polyneuropathies quantified by NDS. In patients with F1-F2 fibrosis, mild polyneuropathy with 3 points NDS (9.1%) predominates, with two cases (9%) being registered with neuropathy of 2 points and 4 respectively, whereas in patients with advanced fibrosis, predominance of polyneuropathy with 2 (13.6%) points NDS, although it also observes a relatively close percentage of mild polyneuropathies with 3 (11.8%) points degree. However, the differences recorded between the two groups are not statistically significant (fig. 2).

When evaluating polyneuropathies at the time of SVR, it is found that most patients have 1 (9.8%) point NDS or 2 (10.6%) points. All patients with F1-F2

fibrosis in whom polyneuropathies were registered have this condition with the 2 points on the NDS, whereas in patients with advanced fibrosis there is a slightly more frequent case of polyneuropathies with 1 (11.8%) point NDS, followed by those with 2 (9.1%) and 3 (2.7%) respectively (fig 2). In this case, also, the differences recorded are not statistically significant (p= 0.195). After SVR it is seen a improvement in the severity of polyneuropathies compared with the previous evaluation. The majority of the cases had polyneuropathy with 1(11.3%) point on the NDS, 2 points is seen in three patients and 3 in four patients (7.7%). Only one case with 4 points NDS polyneuropathy was found. In comparison with previous evaluation we observe that in the subgroup of patients with advanced fibrosis that presented mild polyneuropathies six (11.5%) had 1-point NDS and four (7.7%) presented 3 points , other three patients had 3 (3.8%) and 4(1.9%) points NDS (fig.2). We observe that the severity of the polyneuropathies decreased over time after SVR. The difference observed has statistical significance (p= 002*).

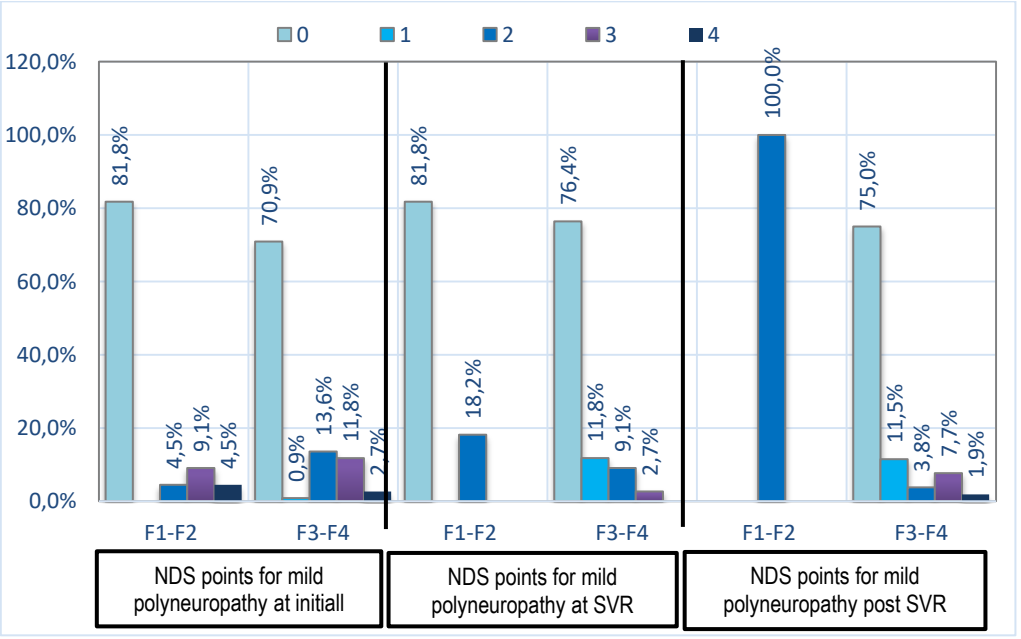

Fig. 2. NDS points of mild polyneuropathy identified in three moment of evaluation in the study group.

DISCUSSION

HCV has been associated along the time with multiple extrahepatic manifestations, the mechanism responsible for these been still partially unknown. It is known that immune response, production of cryoglobulins and antibodies can precipitate CNS and PNS damage. Central lesions are frequently determined by the chemokines and cytokine's that penetrate the hemato-encephalic barrier, affecting the nervous system (15).

The nervous system is not to be consid-

ered a replication site for HCV, very few studies shown in postmortem tissue sample from patients infected with HCV traces of ARN HCV (16, 17, 18). This should bring an inquiry of multiple sites of viral replication.

Clinical signs spectrum of chronic HCV infection is unspecific with few symptoms such as fatigue are present. When the virus involves other systems such as PNS, myalgia and sensorial neuropathies can occur. Axonal lesions and demyelination modulate the clinical spectrum varying from subclinical forms exposed only after electrophysiological studies, to sensitive and motor polyneuropathies. An important percentage varying from 40-70% of the patients with HCV chronic infection experience peripheral neurological damage such as polyneuropathy (19).

In our study we screened patients for PN, polyneuropathy being the neurological extrahepatic manifestation in our lot. The percentage of patients with polyneuropathy and HCV chronic infection was 27.3%. Similar incidence was found in the literature. Thus, Zaltron *et. al* reported an incidence of 30 % (20). A higher incidence in polyneuropathy was seen in those patients with cryoglobulinemia. Migliaresi *et al.* reported 80% of the patients with mixed cryoglobulinemia had polyneuropathy in the absence of metabolic risk factors (21).

Subdividing the study lot based on the degree of fibrosis was necessary in order to verify if other factors except cryoglobulinemia may influence the incidence and the severity of polyneuropathy. No real improvement is seen after 12 weeks of treatment in the group with F1-F2 liver fibrosis, in comparison with the advanced fibrosis group where is seen a regression of clinical symptoms in 5.5% of the patients. Other studies in the literature tried to check for regression of neurological symptoms in other HCV related extrahepatic manifestations. One of these is brain metabolism disfunction, considered as a result of HCV activity. It was observed in a small group of patients treated with Sofosbuvir and Ledipasvir that treatment completion and achieving SVR restored to normal the levels in the brain of N- acetyl aspartate, an important indicator of neuronal dysfunction recovery (21).

Other types of improvement in neurological brain disfunction were identified after achieving SVR after interferon -free regiments. A double-blind placebo randomized clinical trial that included 750 patients with HCV treated with Sofosbuvir and Ledipasvir. An improvement of neurological symptomatology such as fatigue was seen after four weeks of treatment (23). In our study a significant improvement was seen in the period of follow up after achieving SVR. Not only that polyneuropathy decreased in the severity from 4 points NDS to 1 point, but in the early/significant fibrosis group an important reduction (> 90%) of clinical symptomology can be noticed.

It is proven in studies that patients with HCV- related PN and circulating cryoglobulins have a high rate of clinical remission after interferon- free antiviral treatment. This remissible condition, considered to be the main cause of polyneuropathies in these patients has also proven to reaper shortly after the end of the antiviral treatment (24).

CONCLUSIONS

Beyond the liver, patients with HCV chronic infection are exposed to multisys-

temic damage due to serious extrahepatic manifestations. Polyneuropathy remains a concern in these patients influencing negatively the quality of life. After interferon-free therapy serious improvement is seen in HCV infected population regarding the severity of the polyneuropathy but also in clinical symptomatology.

NEWS

DEVELOPMENT OF EFFECTIVE VACCINES FOR ENTEROTOXIGENIC *ESCHERICHIA COLI*

Diarrhea in children is caused mostly by enterotoxigenic *Escherichia coli* (ETEC). Vaccination could be an effective way to prevent ETEC diarrhea. A specific vaccine was not developed yet due to ETEC strains heterogeneity. In The Lancet Infectious Diseases, Firdausi Qadri and colleagues examined the safety and immunogenicity of enterotoxigenic *E. coli* vaccine (ETVAX). ETVAX is an oral, inactivated, vaccine which contains four *E. coli* strains that overexpress adhesins CFA/I, CS3, CS5, and CS6, mixed with a recombinant protein, LCTBA. It previously shown to be safe and highly immunogenic in Swedish and Bangladeshi adults. The study was based on a randomized phase 1/2 trial in children and infants. They showed that ETVAX was safe and well tolerated by children. At a quarter of an adult dose, adverse events like mild vomiting or fever were rare. They observed that the immunogenicity of ETVAX was age-dependent: children aged 12–59 months had significant increases in IgA antibodies in lymphocyte secretions (ALS) targeting all five vaccine antigens, but children aged 6–11 months had significant ALS and fecal IgA responses to only three antigens (CFA/I, CS3, and LTB). The accomplishment of ETVAX in ETEC-endemic regions it's shaded by some concerns like the multitude of ETEC adhesins that are not targeted in the vaccine, or the immunity to the B subunits of heat-labile toxin, but not to the toxic heat-labile A subunit, nor to the heat-stable enterotoxin (Qadri F, Akhtar M, Bhuiyan T, *et al*. Safety and immunogenicity of the oral, inactivated, enterotoxigenic Escherichia coli vaccine ETVAX in Bangladeshi children and infants: a double-blind, randomized, placebo-controlled phase 1/2 trial. *Lancet Infect Dis* 2019; https://doi.org/10.1016/S1473-3099(19)30571-7).

THERAPEUTIC CHALLENGES AND PROGNOSIS INFLUENCE OF CARDIOVASCULAR COMORBIDITIES IN CIRRHOTIC PATIENTS

THERAPEUTIC CHALLENGES AND PROGNOSIS INFLUENCE OF CARDIOVASCULAR COMORBIDITIES IN CIRRHOTIC PATIENTS (Abstract). The effects of advanced liver diseases on heart function, like cirrhotic cardiomyopathy, hepato-pulmonary syndrome or porto-pulmonary arterial hypertension, are well known today. Cardiovascular Diseases (CVD) may affect the liver or increase a pre-existed liver disease in acute or chronic heart failure. The aim of this study was to evaluate the frequency of CV comorbidities in cirrhotic patients and to establish the influence on patients' outcome. **Material and methods**: The current prospective study was conducted over a 16-month period and included 105 patients diagnosed with liver cirrhosis (LC). Patients were extensively analyzed for the presence of CVD, both clinical and echo cardio graphic. **Results**: The main etiology of LC was viral C infection, followed by alcoholic exposure. Dilatative cardiomyopathy, high blood pressure, heart failure with reduced ejection fraction, arrhythmias and deep vein thrombosis were more prevalent in patients with viral liver disease. The valvular diseases were more frequent diagnosed in patients with a worse prognosis (31.4% *vs.* 25.7%, p =0.001), though there were no difference between patients with viral or alcoholic etiology. **Conclusions**: Our study confirmed that there is a high prevalence of different CVD in patients with LC, mostly in patients with viral etiology, and there is a great need for standardized protocols and guidelines for the initial approach, treatment and follow-up of the CV dysfunction in LC patients. **Keywords:** LIVER CIRRHOSIS, CARDIOVASCULAR DISEASES, VIRAL LIVER DISEASE.

Liver cirrhosis (LC) defines the histological reshaping of the liver secondary to a chronic liver injury with the development of regenerative nodules surrounded by fibrous tissue that leads to portal hypertension and end-stage liver disease. Due to its numerous and severe complications, LC represents one of the major causes of morbidity and mortality with a heavy burden on the health care system. The Global Burden of Disease reported an increase in mortality due to cirrhosis complications in the last years with a total of 1 million deaths in 2010 and 1 million due to viral hepatitis

and hepatocellular carcinoma (1). Concerning the cardiovascular diseases (CVD), it is still the first cause of mortality with 17.9 million deaths annually, 31% of all global deaths (2). Taking into consideration the close connections and interactions between liver and heart functions, it is important to routinely assess the CV system on cirrhotic patients, aiming to improve the overall treatment results. It is well known the effect of advanced liver disease on heart function, like cirrhotic cardiomyopathy, hepatic-pulmonary syndrome and porto-pulmonary arterial hypertension. Also, CVD may affect the liver or worsen a pre-existed liver disease in acute or chronic heart failure, either by arterial hypo perfusion in the left-sided heart failure or by passive congestion secondary to increased systemic venous pressure in the right-sided heart failure (3).

CV comorbidities in liver disease represent any simultaneous pathological findings that are neither causes nor consequences of LC but can increase the mortality and have a negative influence on therapeutic outcome. Moreover, the clinical relevance of studying these comorbidities comes from the risks of diagnosis errors that may appear when the two pathologies interfere. Furthermore, the coexisting heart diseases pose important treatment challenges, either by drug interference (i.g.in patients with viral hepatitis C following interferon-free treatment) or drug-induced hepatotoxicity (side effects of CV medication). Given the epidemiological significance, there were conceived comorbidity score systems (CirCom score) that evaluate the total burden of comorbidities on LC patients with a greater mortality prediction(4).

The aims of the current study are to evaluate the frequency of CV comorbidities in LC patients and to establish the influence on patients' outcome.

MATERIAL AND METHODS

The current study was conducted over a 16-month period and included 105 patients (74 men and 31 women), admitted in the Gastroenterology Clinic of "Sf. Spiridon" County Clinical Emergency Hospital (60 patients) and in Infectious Diseases Hospital (45 patients) for LC of various etiologies. All patients were supplementary evaluated in the Cardiology Clinic, where a detailed medical history, physical examination, blood pressure measuring, electrocardiogram recording, and echocardiography evaluation were performed. The data were collected from patients'personal files where they have signed an informed consent regarding the current study. The diagnosis of LC was established based on clinical manifestations and biological, endoscopic and ultrasound changes suggestive for advanced liver disease and portal hypertension and confirmed by a non-invasive method Fibromax or Fibro Scan. Liver function was quantified by Child-Pugh and Model of End-Stage Liver Disease (MELD) scores.

The exclusion criteria were the refusal of patients, patients with pathological conditions that prevented a correct echocardiography examination (thoracic surgery, extreme obesity, severe osteo-articular chest pain), patients with neuropsychiatric pathologies or special socio-cultural beliefs who refused a physical exam or who did not sign the written consent.

The study was conducted in accordance with the Helsinki Declaration and all patients were consecutively enrolled in the study after providing written informed consent.

We assessed the patients using a GE Vivid V7 echocardiograph (2D-echo, M-Mode, pulsed-wave Doppler (PW), continuous-wave Doppler (CW), tissue Doppler (TDI), color Doppler, the parameters being described as follows: (a) Systolic function using ejection fraction (EF) of the left ventricle (LV); (b) diastolic dysfunction (impaired relaxation: E/A<1, E/e' ratio<9, pseudo-normal: E/A > 1 with E/A ratio<1 after Valsalva maneuver and a TDI determined e'/a'<1, E/e'=9-15; restrictive pattern-E/A>2, E/e' ratio >15); (c) Valvopathies visual assessment, color flows, velocities and pressure gradients; (d) dilated cardiomyopathy: LV diameter > 57 mm (or >112% of maximum physiological diameter corrected with age and body surface area) with global heart dilatation and systolic dysfunction (EF<45% and/or fractional shortening (FS)<25%).

All data was statistically analyzed using the *SPSS 20.0*, *Microsoft Excel* 2010 and *EpiInfo* 7®. A p value <0.05 was considered statistically significant.

RESULTS

The patients mean age was 54.6 years and 70.47% were males. We divided our patients into two groups based on age for comparative analysis: aged ≥ 60 years (31.42%) and patients < 60 years (68.58%).

Regarding the etiology of LC, the viral etiology was present in 83 cases (56 men and 27 women, p=0.19) while the alcoholic and mixed (viral and alcoholic) etiology was found only in males (12, respectively 4 cases). Autoimmune origin was more common in females than in males (4 cases compared to 1 case, p= 0.01). We observed an important association between alcoholic etiology of the cirrhosis and male sex (p= 0.01) while the autoimmune etiology was specifically encountered in women (p= 0.01).

As for the relationship between the incidence of specific CV comorbidities and the etiology of LC, dilated cardiomyopathy (DCM) was statistically significant correlated with alcoholic etiology (p= 0.01),high blood pressure (p= 0.01) and heart failure with reduced ejection fraction (p= 0.01). Moreover, there was a statistically significant correlation between viral etiology and the presence of arrhythmias (p= 0.04) and, respectively, deep venous thrombosis/ chronic venous insufficiency (p= 0.04). More detailed information can be found in first table.

TABLE I

Correlations between various cardiac comorbidities and the etiology of cirrhosis

Cardiac pathology	Viral etiology	Toxic etiology	Total	p value
DCM	9 (9.47%)	5 (5.26%)	14 (14.73%)	0.004
HBP	35 (36.84%)	10(10.52%)	45 (47.36%)	0.007
IHD	13 (13.68%)	1 (1.05%)	14 (14.73%)	0.503
HFrEF	10 (10.52%)	5 (5.26%)	15 (15.78%)	0.008
HFpEF	20 (21.04%)	2 (2.1%)	22 (22.14%)	0.564
Valvular diseases	52 (54.73%)	8 (8.42%)	60 (63.15%)	0.787
Arrhythmias	31 (32.63%)	1(1.05%)	32 (33.68%)	0.046
DVT	21 (22.09%)	0	21 (22.09%)	0.048

DCM: dilated cardiomyopathy; HBP: high blood pressure; IHD: ischemic heart disease; HFrEF: heart failure with reduced ejection fraction; HFpEF: heart failure with preserved ejection fraction; DVT: deep vein thrombosis

Analyzing the associated risk factors for CVD, there were important differences between patients with viral etiology versus patients with toxic LC. Metabolic risk factors were highly associated with toxic etiology in terms of increased body mass index (18.07% *vs.* 66.66%, p< 0.01) and the presence of diabetes mellitus (7.22% *vs.* 33.33%, p=0.05). However, the diagnosis of dyslipidemia could not be associated with a specific etiology of cirrhosis (p=0.79). Anemia was common in cirrhotic patients and it also represented a common cause for heart failure decompensation, being significantly correlated with a viral origin of cirrhosis (p= 0.04). Another important CV risk factor was the advanced age, the presence of a toxic LC being highly associated with patients aged over 55 years (p= 0.02).

Following the echocardiography assessment of the diastolic function, the negative modification of this parameter was highly associated with toxic etiology (83.33% with toxic LC *vs.* 53.01% with viral etiology, p= 0.04). The global systolic function of the left ventricle was also modified in patients with toxic LC (p = 0.04) while regarding the pathologies of the aortic or mitral valve there was not significantly correlation with a specific etiology (p= 0.24).

There were certain differences between men and women concerning the CV comorbidities thus pointing out the importance of an individualized approach for every patient. Thus, high blood pressure was more common in cirrhotic females (61.29%in women *vs.*35.13%in men, p = 0.01), as well as the valvular pathology (74.19%in women *vs.*50%in men, p =0.02). On the other hand, deep vein thrombosis was significantly associated with male sex (25.67% in men *vs.* 6.45%in women, p= 0.02). Chronic virus C hepatitis remained the etiology of LC in the majority of patients (36 men and 20 women) without significant difference regarding the gender (p= 0.20). Also, we found no statistically relevant differences between men and women for chronic virus B hepatitis etiology (p= 0.31) or for the ones with a mixed virus B and virus D etiology of LC (p= 0.45).

Regarding the evolution of the patients, 41.90% presented a severe prognosis. Over 1-year monitoring, 9 patients died while out of 34 patients on the liver transplant waiting list, 5 patients have been transplanted (tab. II).

TABLE II

Evolution of the cirrhotic patients according to their cardiac pathology

Cardiac pathology	Deceased/transplant list patients (41.90%)	Stable patients (58.10%)	Total (100%)	p value
DCM	6 (5.71%)	8 (7.62%)	14 (13.33%)	0.938
HBP	14 (13.33%)	31 (29.52%)	45 (42.85%)	0.05
IHD	6(5.71%)	8(7.62%)	14 (13.33%)	0.938
HFrEF	6(5.71%)	9 (8.57%)	15 (15.78%)	0.871
HFpEF	9(8.57%)	13 (12.38%)	22 (20.95%)	0.915
Valvular diseases	33 (31.42%)	27 (25.71%)	60 (57.14%)	0.001
Arrhythmias	10 (9.52%)	22 (23.15%)	32 (32.67%)	0.142
DVT	11 (10.47%)	10(9.52%)	21 (20%)	0.276

DCM: dilated cardiomyopathy; HBP: high blood pressure; IHD: ischemic heart disease: atherosclerosis; HFrEF: heart failure with reduced ejection fraction; HFpEF: heart failure with preserved ejection fraction; DVT: deep vein thrombosis

Negative long-term prognosis was associated with the presence of valvular diseases ($p<0.01$) while an increased blood pressure at the initial examination was a significant marker for a more stable evolution of LC ($p=0.05$). Other CV comorbidities did not present any significant correlations with the outcome of the patients. By analyzing the CV comorbidities among the deceased patients, we found a statistically significant correlation only with the presence of deep vein thrombosis ($p=0.05$).

DISCUSSION

It is known for years that heart and liver are intimately related existing a broad spectrum of acute and chronic CV pathologies that can influence the treatment and outcome of cirrhotic patients. On the other hand, chronic liver injuries can affect heart function in the absence of other CVD or, at least, they may accelerate the natural progression of pre-existing heart diseases. The epidemiological data regarding the etiology of LC and gender distribution revealed similarities with other international studies, but also some particular aspects. Thus, in our study, the vast majority of patients presented a viral etiology (79.04%), followed by a toxic one (11.42%), very similar to the results obtained by Wang *et al.* on a large-scale study (80.62% and 5.68%, respectively) that included 8080 cirrhotic patients (5)highlighting and confirming that emerging countries like China and Romania are areas with a high prevalence of chronic viral hepatitis, opposed to the trend revealed by a study conducted in Germany by Sivanathan V. where the most frequent etiology was related to alcohol consumption (52%) (6).

In this prospective and observational study, we found a very high rate of CVD among cirrhotic patients (80%), many of them being unaware about these diagnoses. More than half of the patients (56.83%) presented diastolic disfunction, an early marker of cardiac dysfunction in the presence of LC. These findings are similar to the ones found by Wong et al (7), its pathophysiological foundation being the initial hypertrophy (due to hyperdynamic circulation) and subsequent fibrosis and myocardial stiffness that alter the left ventricle filling pressures. However, diastolic dysfunction cannot be attributed only to cirrhosis *per se*, but also to DCM, especially the one caused by alcohol abuse. In fact, alcohol may represent a “bridge” between cardiac and hepatic pathology, being an exponent of how diastolic dysfunction can occur via two different pathways.

In our study DCM was highly associated with alcoholic etiology of the cirrhosis ($p=0.04$), further confirming this bidirectional relationship between diastolic dysfunction and liver injury via retrograde congestion. Similar to previous studies demonstrating that diastolic dysfunction precedes systolic dysfunction (8) we observed that only 20% of patients presented an ejection fraction (EF) <50%, being well known that cirrhotic patients generally have a preserved contractility. More interesting, patients with impaired EF were significantly associated with a toxic etiology of cirrhosis ($p=0.042$), basically diagnosed with DCM, but being unmasked in situations with an increased demand for cardiac output associated to impaired myocardial contractility such as in conditions of hemodynamic stress - infections, physical effort, certain medication or surgery (especially liver transplant) (9).

Summarizing the above information, a significant proportion of cirrhotic patients (37.2% of total cases) presented a degree of

heart failure (HF), either with or without systolic dysfunction. Even if toxic etiology of LC was highly associated with DC Mand with HF with reduced EF (p=0.08), viral etiology of the cirrhosis and especially the one caused by hepatic C virus (HCV) presents high interest from the therapeutic point of view. Several studies have previously confirmed an association between hepatitis C virus infection and cardiomyopathy, but none could really establish a pathogenic relationship (10). These issues have arisen because the interferon (IFN)-based therapy for HCV infection has severe cardiac side-effects, thus limiting its use in patients with advanced HF. Promising preliminary results are presented by Poller *et al.* (11) who observed a positive cardiac effect of the new IFN-free regimens in patients with advanced HF (NYHA III-IV classes). They reported a case of a patient with NYHA IV scheduled for heart transplant who entered in NYHA II class at the end of the treatment with an IFN-free medication and heart transplant being no longer considered. The explanation was that HCV was etiopathogenetically involved in myocardial dysfunction for at least two reasons: the IFN-free therapy does not eliminate any other cardiotropic virus (e.g. Coxsackie B3) nor does it have any antifibrotic or cardiac anti remodeling action.

Patients with high BP may develop normal BP during the progression of liver fibrosis due to vasodilatation with low overall systemic vascular resistance and high arterial compliance. In our study 42.8% of patients presented BP>140/90 mmHg at the initial check, more common in women than in men (61.29% *vs.* 35.13%, p= 0.01) and, interestingly, being associated with a better outcome (p=0.05). On the other hand, high BP was incriminated as an independent risk factor for non-alcoholic steatohepatitis, that can progress to cirrhosis, a direct correlation being already proved in multiple studies (12, 13).

Valvular pathology, whether aortic or mitral, is associated with an increased risk in cirrhotic patients, especially in those on transplant awaiting list. If a valve replacement is urgently required (due to acute heart failure or increased risk of sudden death), interventional, minim invasive techniques are preferred, with high advantages in terms of mortality compared to classic surgery (14), mainly because of the high bleeding risk of cirrhotic patients.

Diabetes is probably the most studied comorbidity in cirrhosis, being highly associated with the etiologies related to alcohol abuse and non-alcoholic fatty liver disease. Literature data have shown that diabetes is a predictor of fibrosis, accelerated fibrosis progression, increased liver-related mortality and development of hepatocarcinoma (15). It was also highlighted the synergy between a high alcohol intake and the exacerbated effect of diabetes in cirrhotic patients (16). On12976 Danish cirrhotic patients included in the CirCom study, diabetes without complications was not associated with mortality whereas diabetes with complications did increase mortality (17).Other studies revealed that insulin use was associated with increased risk of hepatocarcinoma and increased mortality, while the use of oral drugs like metformin or thiazolidinediones was linked to a decreased risk (18).Definitely, there are other researches that infirmed the link between diabetes and mortality: a study from the Netherlands including 226 patients diagnosed with cirrhosis in 2001-2011 found that diabetes was not associated with all-cause and liver-related mortality (19). We recorded a similar result in our cohort of 105 patients, diabetes

not being associated to the overall mortality rates.

The limitations of the current study include a small number of analyzed patients, lack of details given specific alcohol intake or exposure to other toxic, the absence of full medical data records to attest liver disease duration, unspecified CV comorbidities or other previous treatments.

CONCLUSIONS

Our study confirmed that there is a high prevalence of different CVD in patients with LC, mostly in patients with viral etiology. New large-scale prospective studies are needed to identify more specific aspects and standardize protocols or guidelines for the initial approach, treatment and follow-up of CV dysfunction in cirrhotic patients.

CONTRAST ENHANCED DIGITAL MAMMOGRAPHY

With the adoption of digital mammography as a replacement for film mammography, work began in the early 2000's to develop a technique that would allow digital mammography to be used with contrast enhancement to depict cancers that would otherwise be occult on standard unenhanced mammography. Those efforts resulted in the development and clinical testing of contrast-enhanced digital mammography (CEDM) using the dual energy subtraction technique. Today CEDM is available commercially for clinical use. It is estimated that over 200,000 CEDM examinations have been performed to date in both research and clinical settings. To perform a CEDM examination, an intravenous is placed in the forearm or antecubital vein and a low osmolar iodinated contrast agent is administered at approximately 3ml/s using a power injector. Contrast agents with iodine concentration between 300 mg/ml and 370 mg/ml are typically used. The volume of contrast is similar to that used for a CT scan, approximately 1.5 ml/kg body weight, typically around 90- 150 ml. After a delay of at least 90 seconds from the end of the injection, the patient is positioned for 2 standard mammography views (craniocaudal and mediolateral oblique) of each breast. Rather than a standard single energy mammogram, however, the CEM device acquires dual-energy image pairs in each projection. Since there is less than 1 second between the low-energy and high energy images, the imaging time is the same as that needed for a standard mammogram. Additional projections may be obtained since optimally enhanced images can typically be obtained up to 7-10 minutes following injection. Following image acquisition, contrast-enhanced subtraction images are produced using a weighted logarithmic subtraction of the low energy image from the high energy image. PULMONARY ARTERIAL PRESSURE IN LIVER TRANSPLANT CANDIDATES. A CENTRE EXPERIENCE AND REVIEW OF LITERATURE (Abstract): Porto-pulmonary hypertension (POPH), characterized by portal hypertension associated with high pulmonary vascular resistance (PVR), represents an important complication in liver cirrhotic (LC) patients. Our study aimed to determine the association between biological profile and pulmonary hypertension in a group of patients on the liver transplant awaiting list. **Material and methods**: The current 3-year prospective study analyzed 60 LC patients admitted for liver transplant evaluation and regular follow-up. All patients underwent biochemical evaluation and LC severity was evaluated by using MELD score and Child-Pugh class. Pulmonary hypertension was determined by standardized echocardiographic evaluation, most important markers being mean and systolic pulmonary artery pressure (mPAP, sPAP). **Results**: Mean age was 50.55 ± 8.3 years, 83.3% males. sPAP was significantly higher in women (24.08±7.76 *vs*. 27.33±13.7 mmHg, p=0.040). The presence of ascites was directly correlated with the severity of pulmonary hypertension (p=0.033) while mPAP was higher in patients with autoimmune LC. mPAP correlated with MELD score (r=0.832, p=0.030), fibrinogen level (r=0.887, p=0.021) and bilirubin level (r=0.758, p=0.045). During the follow-up period, mPAP decreased significantly in patients that received liver transplant. However, mPAP was not a mortality risk factor for the awaiting liver transplant patients. **Conclusions**: Our study revealed that fibrinogen and total bilirubin levels, as parameters of cirrhosis severity, are in direct correlation with mPAP. Furthermore, refractory ascites in end-stage cirrhosis patients could be associated with a higher risk of pulmonary hypertension. Further larger studies on POPH incidence and follow-up in liver cirrhosis are warranted. **Keywords**: PULMONARY HYPERTENSION, LIVER TRANSPLANT, LIVER CIRRHOSIS, ASCITES.

Pulmonary hypertension, characterized as mean pulmonary arterial pressure (mPAP) more than 25 mmHg at rest or more than 30 mmHg during exercise, is often characterized by a progressive and sustained increase in pulmonary vascular resistance that eventually may lead to right ventricular failure (1).

Liver cirrhosis (LC) is one of the numerous conditions that can cause pulmonary hypertension. The association between liver cirrhosis and pulmonary disease consists of a series of vascular changes in the pulmonary vessels due to alterations in distal pulmonary arteries with intimal proliferation, medial hypertrophy, fibrotic changes, plexiform lesions and in situ thrombosis (2). The pathogenesis is still unclear although some of the mechanisms were identified as increasing nitric oxide (NO) levels which determine excessive pulmonary vascular dilatation with secondary ventilation perfusion mismatch (V/Q ratio), intrapulmonary arterio-venous shunt or limited oxygen diffusion (3). There are no medical effective therapies for porto-pulmonary hypertension (POPH), the only reliable treatment being the liver transplant. In the absence of liver transplant the median 24-month survival rate is 23% (4).

POPH represents a form of pulmonary hypertension that is associated with portal hypertension characterized by high pulmonary vascular resistance (PVR) as a consequence of pulmonary vasoconstriction and remodeling. The POPH prevalence in cirrhotic patients is 2-14% (5, 6). The diagnosis is made by right cardiac catheterization by determining the mPAP, the left-sided filling pressures and elevated PVR (>250 dyne/s/cm-5) in patients with cirrhosis and portal hypertension (7, 8). The severity of POPH can be stratified in different risk classes, depending on the mPAP: mild form 25 - 35 mmHg; moderate form 35 - 45 mmHg; severe form >45 mmHg (9). mPAP between 35 and 50 mmHg is associated with an increase in mortality of 50% after liver transplant10. Other studies suggest that in patients with severe form of POPH the mortality is estimated to almost 100% (11). Considering this, liver transplant is indicated only to those who respond to vasodilatory medical treatment with the aim of lowering mPAP below 35 mmHg and a PVR below 400 dyne/s/cm-5 (9). After liver transplant, the pulmonary hypertension is resolved within 6 months at which time medication may be interrupted. In the severe form, mortality after liver transplant is estimated at 42% at 9 months and 71% at 36 months (12, 14). Pulmonary hypertension and cirrhosis are more common among women and patients who also suffer from autoimmune hepatitis and about 5% of the patients with end-stage liver disease will develop pulmonary hypertension (12, 15, 16).

There are no clear clinical factors that determine the risk of POPH in patients with advanced liver disease. Also, the predictors or biological mechanisms responsible for the development of POPH in these patients remain unknown (9, 16, 17). Therefore, the aim of the study was to determine the frequency of POPH in patients with LC on the liver transplant awaiting list and to analyses the patients' biochemical profile in order to identify the relations between biological factors and the severity of the pulmonary hypertension.

MATERIAL AND METHODS

In the current study we have analyzed 60 cirrhotic patients admitted in our institution for liver transplant evaluation and regular follow-up. Patients with other conditions that could lead to portal or pulmonary hypertension or with any pre-existing cardiovascular abnormalities were excluded from the study. The study was conducted as a cross-sectional analysis for a period of three years. The local ethical committee approved the study, and a written informed

consent was obtained from all the patients. The past medical history, clinical examination and laboratory details were obtained from the medical records.

Diagnosis of POPH and patient evaluation

PVR, measured traditionally by right heart catheterization, is an essential parameter of the pulmonary hypertension. However, Doppler echocardiography is an accepted method to evaluate the pulmonary pressure with comparable results. In cirrhotic patients in evaluation for liver transplant this echocardiographic method decreases the requirement of extensive invasive measurements. Our protocol study involved the measurement of the pulmonary pressure by the peak systolic velocity of the tricuspid regurgitation flow and the acceleration time of the pulmonary systolic flow. The current guidelines were used to evaluate all cavities and cardiac volumes. All echocardiographic measurements were repeated three times by the same cardiologist expert. The patients were considered to have pulmonary hypertension by sPAP > 40 mmHg. mPAP was calculated from sPAP (mPAP = 0.61 sPAP + 2mmHg) (18).

All patients were evaluated by abdominal ultrasound and upper digestive endoscopy.

Liver cirrhosis was diagnosed based on clinical signs, biological, ultrasound and endoscopical changes suggestive for portal hypertension and advanced liver fibrosis. MELD score and Child-Pugh score were used to evaluate LC severity.

Biochemical investigations included complete blood count, serum bilirubin, albumin, total protein, prothrombin time/international normalized ratio, liver enzymes (alkaline phosphatase, aspartate transaminase, alanine transaminase, gamma glutamyl transpeptidase), lipid panel, renal function, inflammatory marks such as C reactive protein and fibrinogen.

Statistical analysis

Statistical analysis was performed by using the *SPSS version 21.0* software (SPSS Inc., Chicago, IL, USA). Continuous variables are expressed as mean ± SD and categorical variables as percentages. Biochemical parameters in cirrhotic patients with and without POPH were compared. Quantitative variables with normal distribution were compared using the *Student's t* test. For non-parametric variables, we have used *Mann-Whitney* test. The *Kolmogorov-Smirnov* test was used to check the normality of the data distributions. Chi square test (*Fisher* exact test for small samples) for categorical data was exploited. *Spearman's* correlation coefficient was used to investigate possible correlations between the POPH and different clinical and biological parameters. Statistical significance was considered as p-value ≤ 0.05.

RESULTS

Mean age was 50.55 ± 8.3 years (range 26-63 years), most of them males 83.3%. The first three etiologies of LC were viral B infection (45%), viral C infection (26.7%) and chronic alcohol consumption (16.7%). All patients diagnosed with alcoholic LC had more than 6 months of alcohol abstinence. The majority of patients were classified as Child-Pugh class B (43.3%) with a mean MELD score of 16.9 ± 5.5.

Out of all patients, 5 (8.3%) of them were diagnosed with POPH. In the POPH group 3 were males (60%), viral B infection and autoimmune hepatitis being the most frequent etiologies while the severity

of liver disease was classified in Child-Pugh class B and with mean MELD score 19.9 ± 1.8. The baseline characteristics of the patients included in the study are presented in first table. Alcoholic cirrhosis patients did not present POPH. Among the POPH patients, sPAP values varied from 42 to 55 mmHg.

TABLE I
Baseline characteristics

Parameter	All patients (n = 60)	POPH group (n = 5)	Control group (n = 55)	p-value
Gender, male, n (%)	50 (83.3)	3 (60)	47 (85.4)	0.144
Age, years, mean ± SD	50.55±8.35	54.4±6.22	50.20±8.47	0.641
Etiology of cirrhosis, n (%) HBV HCV Alcohol Autoimmune Other	 27 (45) 16 (26.7) 10 (16.7) 4 (6.7) 3 (5)	 2 (40) 0 (0) 1 (20) 2 (40) 0 (0)	 25 (45.4) 16 (29.1) 9 (16.3) 2 (3.6) 3 (5.6)	 0.246

Albumin (g/l), mean ± SD	3.24±0.74	3.33±0.61	3.23±0.75	0.457
Total Bilirubin (mg/dl), mean ± SD	3.37±3.29	3.66±1.47	3.35±3.43	0.365
Fibrinogen (mg/dl), mean ± SD	271.8±92.1	341.2±93.2	264.7±89.9	0.077
ALT (UI/L), mean ± SD	59.6±51.3	34.0±13.6	62.2±53.1	0.090
AST (UI/L), mean ± SD	81.9±55.1	74.6±44.9	82.7±56.3	0.418
GGT (UI/L), mean ± SD	96.9±84.4	81.2±71.9	98.6±86.1	0.518
Ascites, n (%)	39 (65)	5 (100)	34 (61.8)	**0.033**
HRS, n (%)	7 (11.7)	1 (20)	6 (10.9)	0.396
Encephalopathy, n (%)	15 (25)	2 (40)	13 (23.6)	0.418
Hepatocellular carcinoma, n(%)	15 (25)	0 (0)	15 (27.3)	0.173

There was a statistically significant difference between sPAP in women compared with males (24.08±7.76 *vs*. 27.33±13.7, p=0.040) although this difference has not reach the statistical significance for calculated mPAP (16.91±5.29 *vs.* 19.42±8.1, p=0.140).

Regarding ascites, there has been found a direct correlation between the presence of ascites and the severity of pulmonary hypertension (p=0.033) (fig. 1). There was no difference between the LC etiology and the risk of POPH, although mPAP was higher in patients with autoimmune LC.

Regarding the severity of hepatic cirrhosis assessed by Child-Pugh functional classification, 19.7 % of the patients were in class A, in class B 39.3 % and in class C 36.1 %. A correlation between the severity of pulmonary hypertension (reflected by

the value of sPAP) and Child-Pugh class was investigated. The results revealed that sPAP values were not significantly correlated with Child-Pugh class (p = 0.840).

Regarding all biochemical parameters, there was significant direct correlation between mPAP and MELD score (r=0.832, p=0.030), fibrinogen level (r=0.887, p=0.021) and bilirubin level (r=0.758, p=0.045).

During the follow-up period, 20 patients (33.3%) died, and 10 patients (16.7%) received a liver transplant. Increased mPAP was not a risk factor for mortality on the awaiting liver transplant list.

DISCUSSION

POPH is a recognized subtype of pulmonary arterial hypertension and a complication of LC. However, the majority of the cirrhotic patients did not associate this complication. In fact, even though this complication is in direct relation with portal hypertension, not all the cirrhotic develop POPH (5, 19). In our study, 8.3% of the patients with portal hypertension developed POPH, data that is within the prevalence range reported in the literature (9). Although in our study there were more males with cirrhosis that developed POPH, there was no significant difference observed across gender in the incidence of POPH (p=0.144). However, a study performed in the United States reported a greater incidence of pulmonary hypertension in cirrhotic women11. In our study we found no relation between gender, age, LC etiology and the diagnosis of POPH, results that are rather similar with other reported data (8, 9). However, our result is different with results from other studies that suggested that females are at higher risk of developing POPH (16).

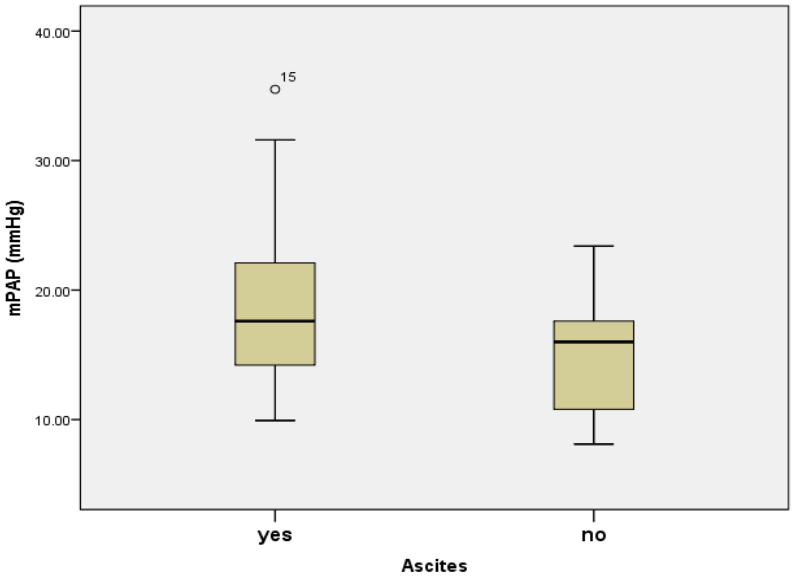

Fig. 1. The relationship between ascites and mPAP

Our study results demonstrated that the severity of LC is related with the development of POPH. We showed that the patients with POPH had a higher Child-Pugh class

and we reported a direct positive correlation between mPAP and the MELD score.

Ascites represents a marker of severity of portal hypertension. In our study, ascites was present in 65% of the patients and had a direct relationship with the severity of the pulmonary hypertension. Other studies showed no correlation but suggested that POPH was more common in patients with refractory ascites and LC possibly due to endothelin-1 excess in the pulmonary circulation (20).

Regarding female patients with POPH and autoimmune cirrhosis, the pulmonary pressure normalized 1 week after the liver transplant and remained normal at 1 month suggesting a good outcome and prognosis. The mechanism of these findings is not fully understood. In many studies, a strong association has been found between portal hypertension and pulmonary hypertension, whether or not liver disease was present. This led to the idea that normalizing the portal pressure could help lowering the pulmonary pressure. Findings in other studies are in concordance with this hypothesis showing improvements and even normalization of the pulmonary and portal pressure after liver transplant. The anatomopathological abnormalities in POPH are rather similar with those described in idiopathic PAH. The most important histological abnormality includes proliferative arteriopathy and necrotizing arteritis, occlusion of the vascular lumen by the smooth-muscle cells or the endothelial cells, and in-situ thrombi formation secondary to a systemic inflammation. The porto-systemic shunts could determine the shunting of the vasoactive substances (endothelin-1, serotonin, interleukin 1, glucagon and secretin) from the splanchnic to the pulmonary circulation. These vasoactive mediators are bypassing the liver metabolism and negatively influence the pulmonary vasculature (21, 22). We demonstrated a direct strong correlation between fibrinogen level as a marker of systemic inflammation and the mPAP. These mechanisms suggest that reversing the portal hypertension could lead to a decrease in pulmonary pressure.

Among the examined laboratory parameters, we found a direct correlation between mPAP and the severity of liver disease assessed by MELD score, fibrinogen level and total bilirubin level. Other studies suggest a correlation between hemoglobin and POPH with a lower value of hemoglobin in the POPH group compared to the non-POPH group (20). This study suggests that hemoglobin level is an independent risk factor for the development of POPH. A decreased hemoglobin leads to a significant cardiac output increase that exacerbates the hyperdynamic splanchnic circulation which is known to be a major contributor to portal hypertension (10). However, in our study no correlation was found between the hemoglobin value and POPH.

Our study has some strengths and also several limitations. Thus, it is one of the few studies examining the incidence of POPH in liver transplant patients. However, the relatively small sample size and lack of long-term evaluation represent limitations to our data.

CONCLUSIONS

In our study, we found no association between gender, age, etiology of the hepatic disease and the development of pulmonary hypertension. The severity of the hepatic disease, fibrinogen level and total bilirubin level are in direct correlation with mPAP in cirrhotic patients. Refractory ascites in end-stage cirrhosis patients could be associated with a higher risk of pulmonary hypertension. Further larger studies on

POPH incidence and follow-up in liver cirrhosis are warranted.

ACKNOWLEDGEMENTS: We thank all the participants in the study.

NEWS

RECENT PROGRESS AND CHALLENGES IN *SCREENING* AND CHARACTERIZATION OF UGT1A1 INHIBITORS

Uridine-diphosphate glucuronosyltransferase 1A1 (UGT1A1) is an important conjugative enzyme in mammals that is responsible for the conjugation and detoxification of both endogenous and xenobiotic compounds. Strong inhibition of UGT1A1 may trigger adverse drug/herb-drug interactions, or result in metabolic disorders of endobiotic metabolism. Therefore, both the US Food and Drug Administration (FDA) and the European Medicines Agency (EMA) have recommended assaying the inhibitory potential of drugs under development on the human UGT1A1 prior to approval. Among the human UGTs, UGT1A1 is of particular clinical significance due to its unique activity in the conjugative detoxification of bilirubin, the endogenous by-product of heme metabolism. Also, UGT1A1 plays a pivotal role in endobiotic homeostasis, in addition to its contribution to xenobiotic disposition and detoxification. Small-molecule inhibitors of UGT1A1 may profoundly influence the catalytic activity of UGT1A1, thereby triggering undesirable effects, like drug/herb-drug interactions (D/HDI) or drug/herb endobiotic interactions: protease inhibitors- indinavir, nilotinib, sorafenib, atazanavir, saquinavir, lopinavir, ritonavir, nelfinavir, tyrosine kinase inhibitors nilotinib, regorafenib, sorafenib, pazopanib, lapatinib, erlotinib, gefitinib and icotinib have been implicated in the development of hyperbilirubinemia, for which UGT1A1 inhibition is the most likely cause. Other drugs levothyroxine, ketoconazole, vitamin A, diclofenac, canagliflozin, diflunisal, gossypol, P-Cresol, herbal extract milk thistle, saw palmetto, echinacea, green tea, epigallocatechin gallate, garlic, ginseng, black cohosh, and valerian, fatty acids, flavonoids, quinine or lignans. Unfortunately, currently commercially available substrates for UGT1A1 (such as bilirubin, estradiol, and etoposide) have different limitations, such as poor selectivity, poor chemical stability, or their use for high-throughput screening (HTS) is unfeasible. Notably, the design principles are already available and experience in the design and development of specific fluorescent substrates for UGT1A1 will surely assist us and other researchers in developing new specific fluorescent substrates for other UGTs. For instance, 1-naphthol was found to be a good fluorescent substrate for UGT1A6, which can be used for HTS of UGT1A6 inhibitors using recombinant enzyme as an enzyme source. However, 1-naphthol can be conjugated by other human UGTs as well, limiting its applications to the recombinant enzyme, rather than use in more complex system such as HLM. Very recently, a set of fluorescent 7-hydroxycoumarine derivatives have been developed as specific substrates for UGT1A10 (an extrahepatic UGT) and at least two of them, appear to work well in tissue preparations. All these findings are very helpful for the design and development of fluorescent probes for different human UGTs, and we hope that more practical fluorescent probes for human UGT enzymes will be successfully developed and used in the near future (Xia LV, Yangliu XIA, Moshe Finel, Jingiing Wu, Guangbo GE, Ling Yang. *Acta Pharmaceutica Sinica B* 2019; 9(2): 258-278).

BETWEEN ETHICS AND UTILITY OF ^{99M}TC HDP BONE SCAN IN CANCER. A RETROSPECTIVE STUDY ON 5,670 PATIENTS

BETWEEN ETHICS AND UTILITY OF ^{99m}Tc HDP BONE SCAN IN CANCER. A RETROSPECTIVE STUDY ON 5670 PATIENTS (Abstract) **Aim:** This paper aims to emphasize the importance of nuclear imaging for cancer patients evolution and personalized treatment. **Material and method:** A retrospective study comprising 5,670 patients, who performed bone scans, between 2003-2015, at the "Sf. Spiridon" County Clinical Emergency Hospital Iași Nuclear Medicine Laboratory. Studied parameters were demographic data, referral diagnosis, staging, tumor markers, bone metastases and patient follow-up. **Results:** Of all, 3,960 were oncological patients. They performed in evolution 3,846 bone scans, between two (21.01%) and 11 (0.05%) explorations. Patients' age varied between 2 and 97 years (with two peaks, at 55 and 65). Gender distribution showed female (61.73%) over male (38.27%) predominance, especially in multiple scans (73.32%). For half of the patients the bone scan showed evolution (worsening), meaning the treatment was only partially effective and required modifications. Ethically, for these patients bone scan was irreplaceable. Its absence would have meant undergoing a partially/inefficient treatment, a reserved prognosis and a shorter survival period. The benefits outweigh the risks in terms of radiation exposure. **Conclusions**: Ethics in oncological nuclear medicine is complex, following the balance between risk and benefit, in the interest of a personalized management. As a result, ethically it is equivalent to maximizing the benefits of this minimally invasive functional investigation, scintigraphy, which is essential for treatment modulation, in order to improve the disease prognosis and increase the patients' survival rate, for precision medicine in cancer. **Keywords**: BONE SCINTIGRAPHY, ETHICS, NEOPLASM, PERSONALIZED TREATMENT, PRECISION MEDICINE.

The ethical issue of using radiation for beneficial purposes, for the patient, was, and still is, under debate in literature (1, 2).

These silent enemies, radiations, that we cannot see, smell, or feel by our senses, with no visible clue of their actual existence, may either be the worst enemy a human may have or the best friend to a patient. As to this point, we can say that the ethical approach in nuclear medicine is equivalent to the risk and benefit balance for a patient (3, 4, 5). The annual effective dose limit for the general population is 1 mSv/year, with an increase of up to 5 mSv/year (special cir-

cumstances) provided as the mean value for 5 consecutive years does not exceed 1 mSv/year. In case of patients, however, the annual dose will be higher compared to the general population, being recommended not to exceed the maxim dosage mentioned by the guidelines (6).

Considering that the value for this category of people is slightly relative, then it assumed to be relative in relation to the diagnosis.

This paper addresses a certain category of patients, diagnosed with osteophilic neoplasms, in which the percentage of primary cancerous tumor dissemination throughout the body at bone level is very high. For this type of patients therapy and evolution depend on patients clinical status, tumor markers, pursuit of bone metastasis and the dissemination degree, and algorithm of diagnosis (3, 4).

What is ethical for the oncologic patient? To do what must be done to ensure a higher survival rate for the patient (5).

OBJECTIVES

This paper aims to support, through a retrospective study, that, for oncological patients, especially patients with osteophilic cancers, in nuclear imaging, ethic means that it is irreplaceable in patients' personalized evolution approach.

MATERIAL AND METHODS

This is a retrospective study conducted over the course of 12 years (between the 1st of January 2003 to the 31st of December 2015) on the patients that had undergone ^{99m}Tc HDP bone scintigraphy and are registered in the archive of the Nuclear Medicine Laboratory "Prof. Dr. Valeriu Rusu" from "Sf. Spiridon" County Clinical Emergency Hospital, from Iasi. The inclusion criteria in this study were the referral diagnosis of neoplasm.

Patients were explored according to EANM guidelines (7), with a dose of 9.6 MBq/kg for adult patients and by using Websters rule for pediatric patients (adult dose x [(age + 1) / (age + 7)]). All well hydrated, according to the guidelines, and voided their bladder immediately before the bone scan. Images were acquired at 2 hours after the radiotracer administration using a dual-head Gamma Camera equipped with low energy high resolution collimators. Usually, whole body images were acquired (acquisition type: anterior/posterior; matrix: 256x1024; zoom: 1.00; speed: 12-14cm/min) and, in relation to the referral diagnosis, patients history and complains, early images, late static images (acquisition type: static; matrix: 256x256; zoom: 1.00; duration:10 minutes) or SPECT images (matrix: 128x128; 180° rotation; zoom: 1.00; 64 view:15 second/view) were also performed. Images were reconstructed by using filtered back projection, Butterwoth filter (cutoff 0.4 cycles/pixels, power 7) or iterative.

Other studied parameters of the patients referred to demographic data, referral diagnosis, staging, tumor markers, follow-up of bone metastases and the clinical/biomarkers evolution of the patient since the last scintigraphy.

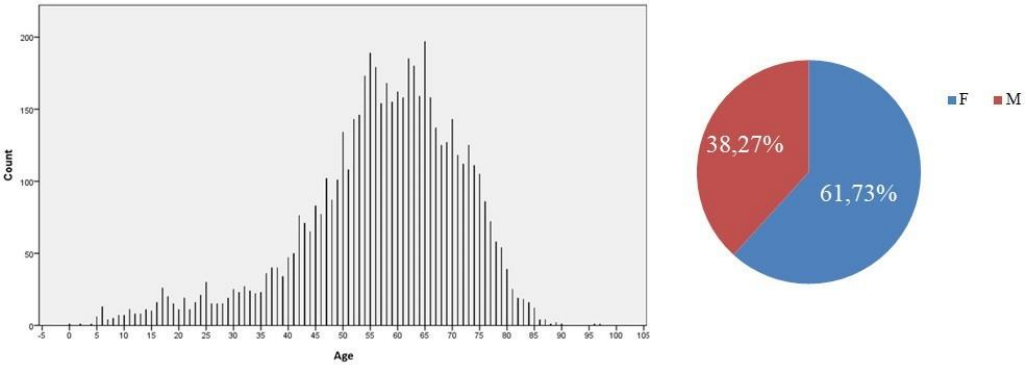
In order to quantify more accurately the evolution of the patients from one scintigraphy to another, an index system was developed, to evaluate the changes: "-2" for patients who had a clearly positive evolution (disappearance of metastases); "-1" for patients with a favorable evolution (incomplete disappearance of metastases); "0" for stable evolution compared to the last investigation; "+1" for patients with new secondary bone

dissemination sites; "+2" for patients with new sites, a negative evolution and an increased degree of radiotracer uptake.

RESULTS

Out of the 5,670 patients examined with bone scan in our laboratory in this period (an average of 454 patients with bone scan per year), approximately 70% (3,960 patients) were oncological patients. 3,846 of them performed in evolution bone scans, between two (21.01%) and 11 (0.05%) explorations. Patients age varied between 2 and 97 years old (with two peaks, at 55 and 65 years). Gender distribution showed female (61.73%) over male (38.27%) predominance, especially in multiple scans cases (73.32%) (fig. 1).

The quantification system makes evidence of differences related with the number of bone scans and from one investigation to another.



a b

Fig. 1. Distribution of age (a) and gender (b) for the patients examined with bone scans

48 patients have undergone at least 5 bone scans, between 2003-2015. In these patients that had undergone at least 5 bone scans, 81.25% females, we determined that the evolution of the primary pathology was negative in half of them, out of which most of them were also females (fig. 2).

By comparison, most of the studied patients had undergone only one bone scan. The percentage of patients that had more than 5 investigations, was diminishing the higher we got (fig. 3). To that end we only found two patients that had the highest number or investigations (11 bone scans).

Comparative analysis of scintigraphic results of patients with multiple presentations determined that the ratio between stationary and evolving cases is 50:50.

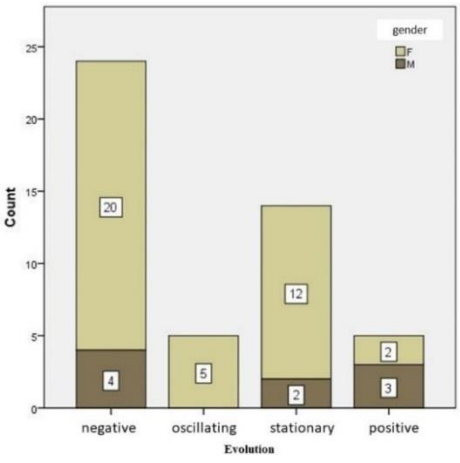


Fig. 2. Evolution of the 48 de patients that had undergone at least 5 bone scans

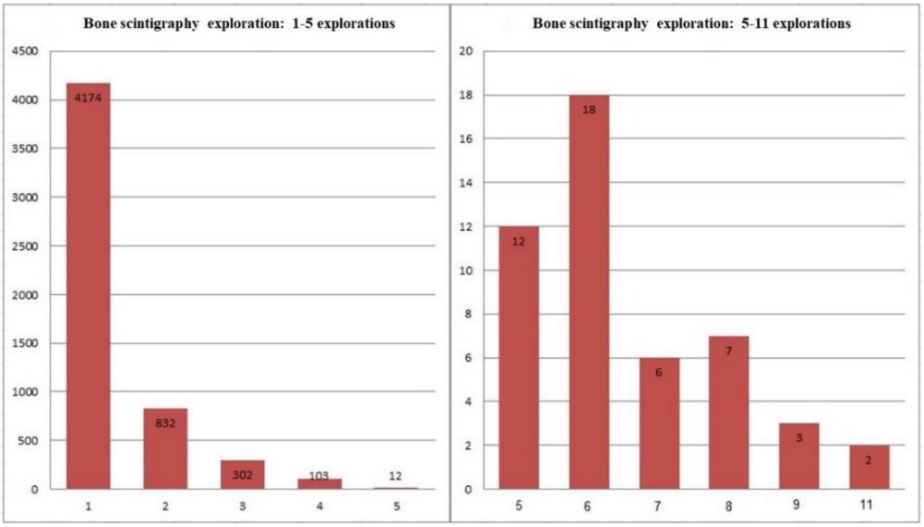

Fig. 3. Number of patients in relation to number of bone scans per patient

Considering the referral diagnoses, almost 40% of cases that we analyzed were with breast cancer and only 14% with prostate cancer. Other referral diagnosis included bronchopulmonary neoplasm, uterine, rectum and bone metastasis. By taking all the referral diagnosis into consideration we concluded that approximately 44.32% of all the investigated cases were breast, ovary and uterine neoplasms (fig. 4).

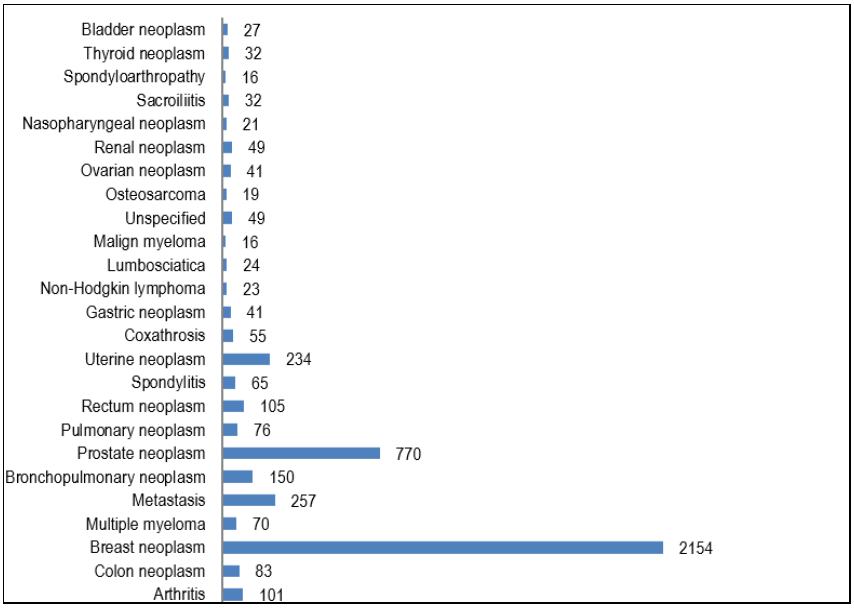

Fig. 4. Patients distribution according to referral diagnosis
(only diagnosis with more than 10 cases were represented)

DISCUSSION

Bone scintigraphy is a noninvasive imaging investigation that studies the biodistribution of the radiotracer at the skeletal level by using bisphosphonates (methylene diphosphonates – MDP; hydroxy ethylene diphosphonate – HDP; hydroxy methylene diphosphonate – HMDP; 2,3 – dicarboxypropane – 1,1 – diphosphonate – DPD; pyrophosphate – PYP) (8,9). Due to the radiotracer uptake mechanism, dependent on local bone vascularization and osteoblastic activity, consisting in the absorption of the radiotracer at the surface of the hydroxyapatite crystals (9), the positive metastases image is evident up to six months earlier on bone scan, in comparison with a correspondent positive image on radiology (where X rays images are related to the tissular densities differences).

This investigation can be indicated for the diagnosis of bone diseases in oncology, rheumatology, bone and joint infections, orthopedics, sports and traumatology, metabolic bone disease, pediatrics (7). The irradiation dose is between 2.9-4.0mSv (300-740MBq) (10), dependent on the administered dose to the patient (9.6MBq/kg). Standard protocol, essentially with whole body delayed images, is generally used, but personalized protocol, with additional images, is possible without other supplementary radiation risks, due to the particularities of imaging in nuclear medicine (the patient is the only source of gamma radiation, after intravenous administration of the radiotracer). The result can give to the practitioner a positive (stationary, non-evolutive cancer - efficient treatment) or negative (evolutive cancer - inefficient treatment, partially or totally) feedback, essential for a personalized treatment approach. The absence of scintigraphy in the latter situation would have led to a bad prognosis and a lower surviving rate. For this category of patients, bone scintigraphy represented a must.

In comparison, in radiology, the X-ray beam is directed toward the patients' body and will be mitigated depending on the tissue density. Bone density modifications will determine positive images on the X ray. However, a whole-body examination is not indicated due to the high irradiation doses to which the patient would be exposed (9). Furthermore, the obtained images offer only structural details but no functional ones.

The MRI can evaluate the structure and the function of the patient's body, by using a whole-body examination which is possible without any kind of radiation (9). Although this is true, the MRI also presents a few limitations such as a high price or limited access to the investigation, in some cases.

Information obtained through X-ray and/or MRI cannot replace but are complementary to the information obtained through bone scintigraphy.

CONCLUSIONS

The ethical approach in oncological nuclear medicine is complex, being equivalent, practically, to following the balance between risk and benefit in the interest of personalizing the patient's treatment. As a result, ethically it is equivalent to maximizing the benefits of this minimally invasive functional investigation (scintigraphy) which is essential for treatment modulation in order to improve the prognosis of the disease and increase the patient's survival rate.

CONFLICT OF INTERESTS AND FUNDING

The authors declare that there is no conflict of interest and they received no specific funding regarding this scientific research.

NEWS

RISK OF COVID-19 IN PATIENTS WITH AUTOIMMUNE INFLAMMATORY RHEUMATIC DISEASES

There is a continuous debate whether patients with autoimmune inflammatory rheumatic diseases (AIRD) treated with disease-modifying anti-rheumatic drugs (DMARDs) are more susceptible to COVID-19 infection. In their prospective observational study, Nuñez *et al* described patients with AIRD from a Madrid hospital who were positive to COVID-19 during the pandemic peak. The results are reassuring: the use of DMARDs does not seem to be followed by a higher hospital admission related to COVID-19, so they do not pose a risk of contracting the virus. Patients admitted more frequently were naïve to anti-TNF-alpha agents; in this respect, the IL-6 inhibitors (tocilizumab, sarilumab) have proven beneficial in patients with SARS-CoV-2. On the other hand, the data showed that older age, comorbidities and the presence of AIRD increased the risk of hospitalization compared to the non-rheumatic population. (Nuñez DD, Leon L, Mucientes A, *et al.* Risk factors for hospital admissions related to COVID-19 in patients with autoimmune inflammatory rheumatic diseases. *Annals of the Rheumatic Diseases* 2020; 79(11): 1393-1399).

RISK FACTORS OF INFLUENZA A AND B VIRUS INFECTION IN CHILDREN POPULATION FROM SOUTH- EASTERN AREA OF ROMANIA

RISK FACTORS OF INFLUENZA A AND B VIRUS INFECTION IN CHILDREN POPULATION FROM SOUTH-EASTERN AREA OF ROMANIA (Abstract): The objective of this study was to identify clinical and paraclinical characteristics along with risk factors in patients with influenza A and B virus infection. **Material and methods:** This retrospective study included children diagnosed with influenza, admitted to the pediatric department of Constanta Infectious Diseases Clinical Hospital, from Romania, during the 2015-2019 influenza cold seasons. Data regarding clinical characteristics, laboratory tests (fibrinogen, white blood cells (WBC), hemoglobin (Hb), platelets (PLT), erythrocyte sedimentation rate (ESR), creatine-kinase (CK), alanine aminotransferase (ALT), aspartate aminotransferase (AST) and C-reactive protein (CRP), and management were collected. **Results:** Over the study period, 265 patients with influenza A and 83 patients with influenza B were investigated. The mean age of patients with influenza A was higher than of patients with influenza B (6.48 vs 5.9 years). It has been showed that cough was statistically different in both types ($p=0.0094$). The same statistically significant values were seen for rhinorrhea ($p=0.0035$), vomiting/nausea ($p=0.0362$), dyspnea ($p=0.0449$), myalgias ($p=0.0412$) and pneumonia ($p=0.0077$). At admission, the laboratory tests showed higher values of fibrinogen in A influenza and higher values of WBCs in B influenza. Hemoglobin, PLT, CK, and AST shows a significant difference for B influenza ($p<0.001$). In contrast, CRP shows significant differences of values for A influenza ($p=0.001$). Moreover, the early antiviral treatment was almost similar for both influenzas early from the onset ($p=0.0418$). **Conclusions:** Although we have found the predominance of clinical characteristics and non-specific inflammation markers as risk factors in patients with influenza A virus, the predisposing to influenza B should be paid also attention. This information's should be used in order to optimize its utilization for early effective and preventive management strategies in pediatric population.
Keywords: INFLUENZA A VIRUS, INFLUENZA B VIRUS, CLINICAL, LABORATORY, CHILDREN.

The influenza ribonucleic acid viruses showed to have an important impact not only for seasonal endemic infections but also for pandemic outbreaks (1, 2). These types of viruses present significant immunogenic proteins on their surface. Due to their segmented genome, it allows these viruses to make antigenic shift changes, which leads to weakening of the adaptive immune system for a range of avian, mammalian species, and humans (1). In humans, there are three specifically types of influenza strains: A, B and C (3, 4). The higher incidence of influenza A and B was seen in major of children around the world (5, 6). Concerning influenza B virus, some studies have sustained the fact that this virus can lead to some limited respiratory infections (7), and sometimes being even similar with the symptomatology of influenza A virus, considering the same rate of hospitalization and death rates (8, 9). The variations of specific viruses type in pediatric population shows a direct relationship with child's age (10). Interestingly, a higher attention was seen for influenza A virus in comparison with B influenza, noticed the fact that B virus could be less virulent with a lower pandemic potential (11, 12). Considering this task, in the last decades, some studies have been reported more clinical features between A and B influenza, in which B virus presenting only a limited higher level of severity (13, 14). The objective of this study was to identify clinical and paraclinical characteristics as risk factors in the patients with influenza A and B virus infection admitted to the pediatric infectious diseases department for early preventive management strategies.

MATERIAL AND METHODS

This retrospective study included 348 children treated for A (n=265) or B (n=83) influenza in the infectious diseases children department of Constanta Clinical Infectious Diseases Hospital from Constanta, Romania with mean aged of 6.48 for A influenza and 5.9 for B influenza, which required hospitalization.

Eligibility criteria were children's aged ≤16 years diagnosed with laboratory confirmed influenza A or B during the epidemic season, between January 2015 and May 2019. Patients with unidentified flu represented the exclusion criteria.

The clinical characteristics related to fever, cough, rhinorrhea, vomiting/nausea, diarrhea, dyspnea, myalgia, pneumonia, or bronchiolitis were collected. The diagnosis of pneumonia was established by acquiring abnormalities data from chest X-ray or pulmonary computed tomography (CT) scan.

The laboratory tests collected included fibrinogen (normal range (nr) = 150-400 mg/dl), white blood cells (WBCs, nr = 6-17/10*9/L), hemoglobin (Hb, nr = 11-14 g/dL), platelet (PLT, nr = 150-400/10*9/L), erythrocyte sedimentation rate (ESR, nr = 3-9 mm/1 h), creatine-kinase (CK, nr = 24-195 U/L), alanine aminotransferase level (ALT, nr = 0-40 U/L), aspartate aminotransferase level (AST, nr = 0-37 U/L) and C-reactive protein (CRP, nr = 0-5 mg/L).

The indication for hospitalization included fever, and respiratory symptoms (i.e., cough or pneumonia). Oseltamivir as antiviral agents were generally prescribed in the cases where children had positive PCR for influenza A or B virus. All patients recovered without complications.

Agreement of Ethic Committee from Constanta Infectious Diseases Clinical Hospital from Romania and informed con-

sent of patients and parents were obtained.

Statistical analysis

Comparison of proportions were performed by chi-squared test for the comparison of two proportion (from independent samples), expressed as percentage, and the comparation of mean values of continuous variables were performed by independent samples t-test.

When the calculated p value is less than p= <0.05 the conclusion is that the 2 proportions are significantly different, respectively the two means do differ significantly.

RESULTS

A number of 265 patients with influenza A and 83 patients with influenza B viruses were included in the study (fig. 1), in which patients with unidentified flu were excluded.

The mean age of the patients with influenza A was higher than that of patients with influenza B (6.4 *vs.* 5.9 years), the majority being found in 2016 (January-March) and 2019 (January- May).

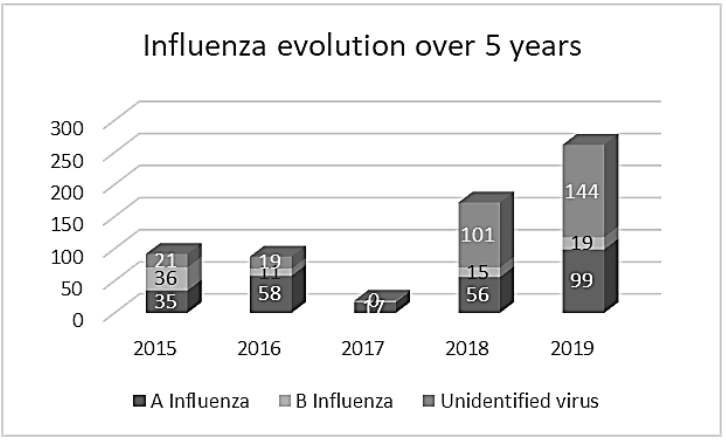

Fig. 1. The evolution of influenza A, B, and unidentified flu in pediatric patients.

Clinical manifestation like fever was found predominantly in influenza B virus and vomiting/nausea, diarrhea, dyspnea, myalgia, pneumonia and bronchiolitis in influenza A (tab. I).

It has been showed that cough was statistically different in both types (i.e., 63.39% in influenza A *vs.* 79.51% in influenza B, p=0.0094). The same statistically significant values were seen for rhinorrhea (i.e., 73.2% *vs.* 55.42%, p=0.0035), vomiting / nausea (i.e., 77.35% *vs.* 65.06%, p=0.0362), dyspnea (i.e., 18.49% *vs.* 8.43%, p=0.0449), myalgia (i.e., 46.03% *vs.* 32.53%, p=0.0412) and pneumonia (i.e., 67.54% *vs.* 50.6%, p=0.0077). The laboratory tests showed higher values of fibrinogen in A influenza case and higher values of WBCs for B influenza (308.82 *vs.* 298.95 and 3,857.28 *vs.* 4,068.23). Hemoglobin (i.e., 10.96 *vs.* 12.16), PLT (i.e.,182846.73 *vs.* 215480.95), CK (i.e., 316.01 *vs.* 408.31), and AST (i.e., 45.61 *vs.* 51.66), shows a significant difference for B influenza comparing with A influenza (p<0.001). In contrast, CRP shows significant differences of values for A influenza (i.e., 7.05 *vs.* 5.53, p=0.001). Moreover, ESR values showed similar values for both A and B influenza (tab. II).

TABLE I

Clinical characteristics and diagnosis by influenza type

Clinical characteristics	Influenza type		χ^2_{calc}	*p value*
	A (n = 265)	B (n = 83)		
Fever	198 (74.71%)	69 (83.13%)	2.059	0.1513
Cough	168 (63.39%)	66 (79.51%)	6.742	0.0094
Rhinorrhea	194 (73.2%)	46 (55.42%)	8.522	0.0035
Vomiting / Nausea	205 (77.35%)	54 (65.06%)	4.39	0.0362
Diarrhea	51 (19.24%)	11 (13.25%)	1.167	0.2800
Dyspnea	49 (18.49%)	7 (8.43%)	4.022	0.0449
Myalgias	122 (46.03%)	27 (32.53%)	4.170	0.0412
Pneumonia	179 (67.54%)	42 (50.6%)	7.112	0.0077
Bronchiolitis	27 (10.18%)	5 (6.02%)	0.86	0.3538

TABLE II

Laboratory results of patients by influenza type

Test	Influenza type		p value
	A (n = 265)	B (n = 83)	
Fibrinogen (mg/dL)	308.82	298.95	0.110
WBC (/10*9/L)	3,857.28	4,068.23	0.115
Hb (g/dL)	10.96	12.16	<0.001
PLT (/10*9/L)	182,846.73	215,480.95	<0.001
ESR (mm/1 hr)	13.87	13.53	0.605
CK (U/L)	316.01	408.31	<0.001
ALT (U/L)	45.54	47.72	0.148
AST (U/L)	45.61	51.66	<0.001
CRP (mg/l)	7.05	5.53	0.001

Values are presented as mean values. WBC = white blood cells; Hb = hemoglobin; PLT = platelets, ESR= erythrocyte sedimentation rate; CK = creatine- kinase; ALT = alanine aminotransferase; AST = aspartate aminotransferase; CRP = C-reactive protein.

Approximately the same number of patients from both influenza types received prescription for early antiviral treatment with Oseltamivir (60.37% for influenza A *vs.* 73.49% for influenza B (tab. III). Furthermore, about 35.09% from influenza A and 49.39% from influenza B received antibiotics (p=0.0273) and 30.18% from influenza A and 18.07% from influenza B, received corticosteroids (p=0.0434).

TABLE III

Management of patients with A and B influenza

Management	Influenza type		χ^2_{calc}	*p value*
	A (n = 265)	B (n = 83)		
Early antiviral treatment (<48 hours from the onset of symptoms)	160 (60.37%)	61 (73.49%)	4.145	0.0418
Antibiotics	93 (35.09%)	41 (49.39%)	4.871	0.0273
Corticosteroid therapy	80 (30.18%)	15 (18.07%)	4.081	0.0434

DISCUSSION

Influenza showed to be a self-limited disease in children, being associated with higher mortality rates, especially school aged children, considered that the prevalence of A influenza increased according to age similar with other studies and noticed in our previous studies also (15, 16, 17).

Regarding the influenza spreading, in temperate area the influenza appears in winter contrary to other disease like Boutonneuse fever, which is a seasonality of disease with a peak during the summer (18).

The most common months with the largest number of severe influenza virus infection cases in our study were from January to March, and just in year 2019 we noticed cases also in April and May.

Moreover, the presence of a greater increase in both laboratory tests and early treated patients was seen for influenza B virus, contrary to that of influenza A which is associated with more severe outcomes (11, 19). This could be explained by the fact that patients with influenza A were older than patients with influenza B (6.48 *vs.* 5.9), which is in accordance with the results of other studies (14, 20, 21). Another study sustains that patient much younger (i.e., less than 6 months) had a higher mortality rates than those aged between 13 and 17 years (22). The value of liver aminotransferases, AST and ALT were slightly elevated like in many infectious diseases with systemic involvement (23) but not elevated like in an acute viral hepatitis caused by A hepatitis virus (24). The findings from our study and previous studies from the same region confirm a high burden of acute disease in Romania and provide useful data to support the implementation of vaccination (25).

In our study, the predominance of influenza was A from our region, which is in accordance with other studies which show that influenza A was the predominant type of influenza in both Australia and the United States (22, 26).

Usually, the complications of influenza A and B are characteristics for acute respiratory distress syndrome, being accompanied with death (27, 28). In our study, although the majority of clinical parameters presented higher values for influenza A, it seems that influenza B showed to have a higher impact on the health of our pediatric population sustained by the laboratory test results.

In the case of influenza B infection, some authors have been showed from CT features bilateral diffuse ground-glass opacities besides lung pathology of diffuse alveolar damage (29), changes similar to other pulmonary disease like tuberculosis (30, 31) pulmonary hypertension (32) or cancer (33). However, in our study the most common chest X-ray changes were

like in an interstitial pneumonia suggestive for features of influenza.

Another study sustained the fact that myalgia is a symptom that belongs more to influenza B virus (34). Although there have been few studies which reported important results regarding muscle-derived enzymes (35), together with neurological exam, urine myoglobin, localized myalgia in legs, and/or renal function, our study shows just a slightly increase in CK levels among patients with important myalgias. Moreover, clinical features like myalgia were seen more predominantly in influenza A virus.

The antiviral treatment was almost similar early administered in less than 48 hours (i.e., 60.37% for influenza A and 73.49% for influenza B), considering the fact that in children infection is nonspecific, being difficult to differentiate from other respiratory infection. However, the early administered treatment showed to have many benefits on symptoms (36, 37, 38).

The antibiotics were given in approximately 35.09% in influenza A and 49.39% in influenza B patients and corticosteroid treatment in 30.17% for influenza A and 18.07% for influenza B patients. Therefore, pediatric clinicians should pay more attention on these patients, giving them an early treatment for influenza for those suspected. The initiation of corticosteroid therapy still remains controversial. Although some studies sustained the fact that corticosteroids can decrease mortality (39, 40), other studies have been found that this treatment can lead to poor outcome (41-43). In our study corticosteroids were recommended in patients with flu complicated with bronchiolitis and myositis. Although there were registered different complication like bacterial pneumonia, bronchiolitis or myositis evolution was favorable in all cases, no death being registered.

CONCLUSIONS

Early recognition of clinical symptoms and laboratory features as risk factors of both influenza A and B, as in our present study, could provide an effective management and outcomes in pediatric population. Although we have found the predominance of both clinical characteristics and nonspecific inflammation markers in influenza A virus patients, the predisposing to influenza B should be paid also attention. Since influenza can be prevented by vaccine it should be routine encouraged in children like in adults in order to prevent future hospitalization cases.

UTILITY OF THE INTERNATIONAL PHYSICAL ACTIVITY QUESTIONNAIRE IN PATIENTS WITH HEART FAILURE - THE EXPERIENCE OF A CARDIOVASCULAR REHABILITATION CLINIC (Abstract): Cardiac rehabilitation is a multidisciplinary program that improves health-related quality of life and exercise capacity in patients with heart failure. The International Physical Activity Questionnaire - Long Form (IPAQ-L) is an instrument for monitoring population levels of physical activity. The aim of our study was to evaluate the utility of IPAQ-L in rehabilitation of patients with heart failure. **Material and methods:** We performed a single-center cross-sectional study on 119 patients in which we evaluated anthropometric parameters and cardiovascular risk factors such as smoking, alcohol consumption, blood pressure profile, glycemic, and lipid profile. The physical activity level was determinate by applying IPAQ-L. **Results:** Factors that correlate with better levels of physical activity were younger age ($p = 0.013$), weight status ($p = 0.028$), and abdominal circumference ($p = 0.007$). The application of the IPAQ questionnaire showed that 79.8% of the subjects performed physical activity at a level of at least 1,500 MET-minutes/week. **Conclusions:** Within a cardiac rehabilitation program, IPAQ-L can be used to assess physical activity, being an instrument with reasonable measurement properties for national monitoring. **Keywords:** CARDIAC REHABILITATION, HEART FAILURE, IPAQ, PHYSICAL ACTIVITY.

Cardiac rehabilitation is a therapeutic option for patients suffering from a variety of heart conditions. Although the cardiovascular rehabilitation program was initially targeted for patients with coronary artery disease, the range of cardiovascular and metabolic pathologies that benefited from it, grew significantly over time, with an improvement of the patient's quality of life, including increased exercise capacity and physical activity. Its prescription in these situations is backed up by large evidence

that shows improved clinical results. Despite this data, cardiac rehabilitation referral and attendance remain low, requiring the development of actions to promote its practice (1).

According to a 2020 study, quantification of cardiac rehabilitation can be made using International Physical Activity Questionnaire (IPAQ). The variability in moderate to vigorous physical activity and sedentary behavior as measured by IPAQ or accelerometer, can objectify a community's health status (2).

The patient's ability to evoke and identify their recent PA as light, moderate or vigorous is a fundamental limitation of self-report surveys. The IPAQ questionnaire has been verified in 14 locations across 12 nations and offers consistent PA measurements. IPAQ is available in two versions. While the IPAQ Short Form (IPAQ-S) is advised for ample prevalence studies, the IPAQ Long Form (IPAQ-L) allows for a more extensive study of PA across four domains: occupation, transportation, home, and leisure time (3).

The ***aim*** of our study was to evaluate the usefulness of IPAQ-L questionnaire in patients with heart failure included in a cardiac rehabilitation program. Also, we wanted to assess the link between the IPAQ-L questionnaire items and the patients' clinical, biochemical, and paraclinical variables and the impact of cardiovascular comorbidities such as obesity, hypertension, and type 2 diabetes on IPAQ-L outcomes.

MATERIAL AND METHODS

We performed a single-center cross-sectional study that lasted 12 months (1 January 2017 - 31 December 2017), including patients with various cardiovascular pathologies, who had previously undergone cardiovascular recovery programs and received advice on lifestyle changes and control of risk factors. The patients included in the study were at least at the second hospitalization in the Cardiovascular Rehabilitation Clinic from the Clinical Rehabilitation Hospital, Iasi, Romania. Anthropometric parameters, cardiovascular risk factors (smoking, alcohol consumption, blood pressure profile, glycemic and lipid profile), exercise capacity (exercise test), quality, and quantity of physical activity performed by applying the International Physical Activity Questionnaire have been assessed.

The local Ethics Committee for Scientific Research of the "Grigore T. Popa" University of Medicine and Pharmacy Iasi (certificate of approval: 5483/8 March 2017) and the Ethics Committee for Scientific Research of the Rehabilitation Clinic Hospital (certificate of approval from 27 January 2017) gave their approval for the clinical investigation to be performed. All the patients signed an informed consent form.

RESULTS

The study included 119 patients, with a mean age of 57.9 years (minimum 34 years, maximum 82 years), the gender ratio being balanced (50.4% men). All of the descriptive statistics can be observed in first table. The application of the IPAQ questionnaire showed that 79.8% of the subjects performed physical activity at a level of at least 1,500 MET-minutes/week.

Factors that correlate with better levels of physical activity were younger age ($r = -0.222$, $p = 0.013$), weight status (weight $r = 0.202$, $p = 0.028$), and abdominal circumference ($r = 0.245$, $p = 0.007$). Physical activity did not correlate with the effort

capacity evaluated objectively by exercise test (r = 0.053, p = 0.569). No significant differences were found, in terms of the level of physical activity performed, for different associated cardiovascular risk factors: hypertension (p = 0.259), diabetes (p = 0.483), alcohol consumption (p = 0.286). No significant differences were found between the genders in terms of physical activity (p = 0.559).

TABLE I

Descriptive statistics of the studied population

	Total	Males	Females	p-value
Number	119	60 (50.4%)	59 (49.6%)	
Age (years)	57.9 (± 7.5)	58.2 (± 8.3)	57.7 (± 6.7)	0.707
Weight (kg)	83.5 (± 12.4)	88.0 (± 12.0)	78.9 (± 11.2)	<0.001
BMI (kg/m^2)	30.2 (± 4.7)	29.6 (±5.0)	30.7 (± 4.4)	0.211
AC (cm)	98 (± 12.9)	101.1 (± 14)	94.8 (± 10.9)	0.007
SBP (mmHg)	134.1 (± 15.5)	132.4 (± 17.5)	135.9 (± 12.9)	0.213
DBP (mmHg)	83.5 (± 10.4)	83.6 (± 10.0)	83.5 (± 10.8)	0.955
Glycemia (mg/dL)	116.9 (± 39.0)	124.8 (± 43.2)	108.6 (± 32.2)	0.022
TC (mg/dL)	200.1 (± 42.7)	191.4 (± 45.2)	208.9 (± 38.3)	0.024
HDL-C (mg/dL)	48.3 (± 13.3)	45.5 (± 12.3)	51.2 (± 13.7)	0.020
LDL-C (mg/dL)	121.8 (± 37.5)	116.3 (± 39.0)	127.5 (± 35.4)	0.120
Non-HDL-C (mg/dL)	151.5 (± 40.4)	146.0 (± 43.0)	157.3 (± 37.0)	0.127
TG (mg/dL)	163.1 (± 113.2)	169.9 (± 133.7)	156.3 (± 88.1)	0.515
Hypertension	95 (79.8%)	43 (36.1%)	52 (43.7%)	0.021
Diabetes	36 (30.2%)	25 (21%)	11 (9.2%)	0.005
Alcohol	12 (9.2%)	11 (8.4%)	1 (0.8%)	0.005
Smoking	26 (21.8%)	23 (19.3%)	3 (2.5%)	<0.001
LVMI (g/m^2)	119.4 (± 36.0)	128.4 (± 35.2)	108.4 (± 33.4)	0.006
%HR (%)	74.8 (± 12.4)	72.4 (± 11.4)	77.2 (± 13.0)	0.033
Exercise resistance (W)	89.4 (± 30.0)	103.1 (± 30.3)	75.4 (± 22.4)	<0.001
Workload (METS)	4.8 (± 1.3)	5.1 (± 1.4)	4.54 (± 1.2)	0.026
MET-min/week	10193 (± 11165)	10790 (± 12119)	9586 (± 10171)	0.558

BMI: body mass index, AC: abdominal circumference, SBP: systolic blood pressure, DBP: diastolic blood pressure, TC: total cholesterol, HDL-C: high-density lipoprotein cholesterol, LDL-C: low-density lipoprotein cholesterol, TG: triglyceride, LVMI: left ventricular mass index, MET: metabolic equivalent of task

From the point of view of physical activity, no statistically significant differences were observed between patients who consumed alcohol (13,630 ± 13,697 MET) and those who did not (9,843 ± 10,854 MET) (fig. 1). In addition, there was no

statistical significance when talking about the association of physical activity with the ones diagnosed with diabetes mellitus (11,422 ± 13,404 MET) and the ones that do not associate this disease (9,660 ± 10,087 MET) (fig. 2).

Similar findings without statistically significant differences were observed between patients diagnosed with hypertension (10,663 ± 11,812 MET) and those without hypertension (8,332 ± 8,049 MET) when performing physical activity (fig. 3).

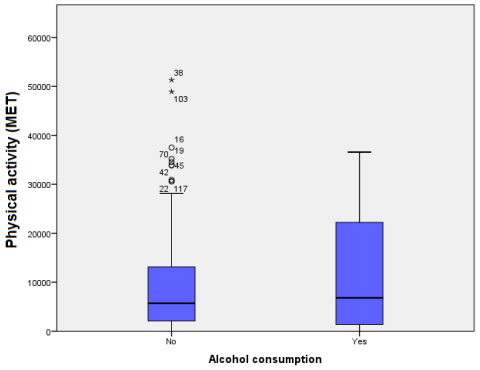

Fig. 1. The correlation between alcohol consumption and physical activity (MET)

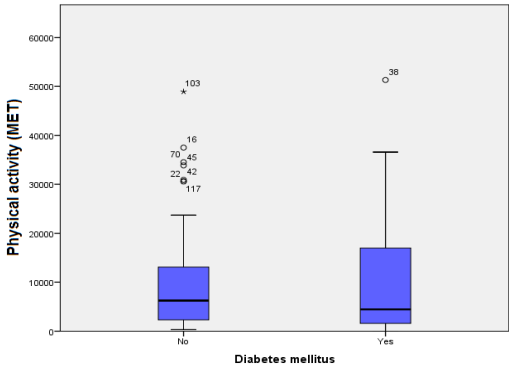

Fig. 2. The correlation between diabetes mellitus and physical activity (MET)

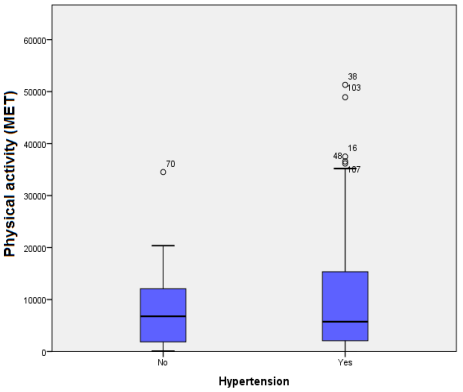

Fig. 3. The correlation between hypertension and physical activity (MET)

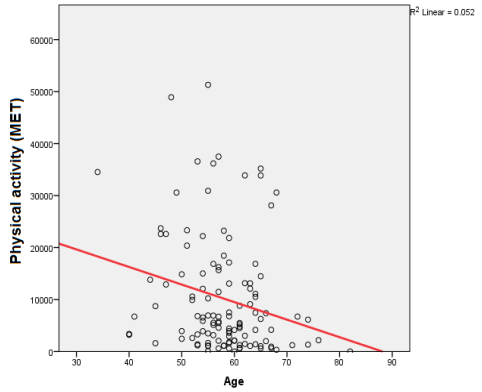

Fig. 4. The correlation between age and physical activity (MET)

We can observe a negative statistically significant correlation between age and physical activity, this being a well-known fact that once the patients get older, they have a lower capacity of performing the same amount of physical activity compared to a young adult (fig. 4).

A positive statistically significant correlation was found between physical activity and waist circumference and weight, respectively (figs. 5, 6). Basically, the patients with overweight and obesity spent

more time performing intensive physical activity, this happening because they are enrolled in a cardiac rehabilitation program.

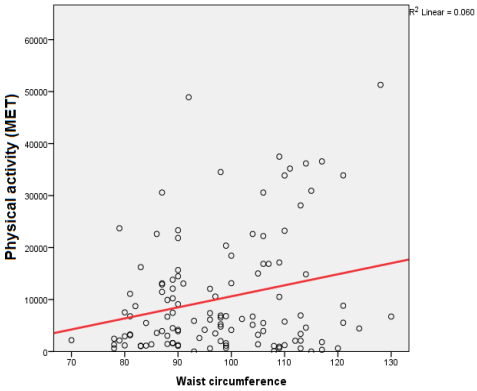

Fig. 5. The correlation between waist circumference and physical activity (MET)

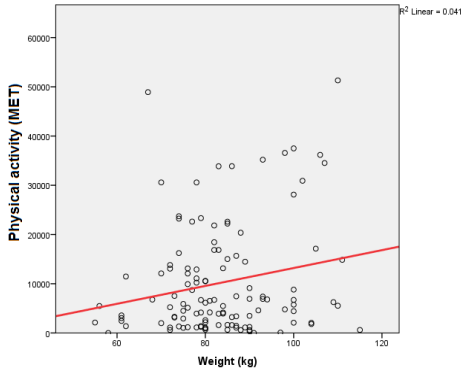

Fig. 6. The correlation between weight and physical activity (MET)

DISCUSSION

The IPAQ questionnaires were investigated in both developed and developing countries' urban populations. Therefore, attention is suggested when analyzing IPAQ data from rural or low-literacy areas in underdeveloped nations (4). Despite the fact that the IPAQ-L has been validated for PA assessment in individuals over 18 years of age (4), it loses reliability, like most self-reported techniques of detecting PA levels, since patients usually exaggerate their PA levels (5). For example, the IPAQ-L overestimates moderate to vigorous PA while underestimating the sitting time (6, 7). Therefore, we opted to adopt this strategy in our analysis because recent studies found that subjects interviewed by a professionally trained person, reported PA levels that were significantly closer to the true ones than those who filled out the IPAQ questionnaire on their own (6).

Even though IPAQ-L has been linked to an exaggeration of overall physical activity in comparison with the IPAQ Short Form (3), its benefit lies in its ability to distinguish domain-related physical activity, providing a complete analysis of the research group's activity patterns. Such information could be valuable in developing successful sedentary behavior intervention strategies (8).We found no significant link between BMI or AC and weekly PA in the investigated domains, despite previous publications reporting a negative correlation among levels of physical activity and BMI (9).

Men engage in more moderate to vigorous daily effort (primarily occupational and leisure-related) than women, according to a study published in 2019 (9). Women spend little time practicing PA, which is mostly in household-related domains. Despite the fact that gender has been shown to have a significant impact on the amount and type of physical activity, both men and women in our study participants expended equivalent physical effort, as measured by the IPAQ questionnaire. In the household and garden domains, the difference in the amount of vigorous physical activity con-

ducted by men versus women approached borderline correlation.

Even if prior research has demonstrated an age-related decline in physical activity (10, 11), our study only identified a moderate relationship. Although many researchers have found an inverse relationship between physical activity and excess weight (12, 13), other studies have found an unusual positive relationship between total physical activity and body mass index (particularly among women), which could be described by changing lifestyles or noticeable determination (14, 15, 16).

In a study published in 2016 (17), the authors investigated the use of IPAQ-L in persons with type 2 diabetes, including both the ones who have been diagnosed with peripheral neuropathy but also the ones who do not have this disease. Individuals with type 2 diabetes diagnosed with peripheral neuropathy were found to be considerably less active compared to those with type 2 diabetes alone ($p = 0.04$), according to the researchers. A study published by Mynarski *et al.* that compared the direct physical activity measurement with IPAQ versus indirect physical activity evaluation with an accelerometer in type 2 diabetes patients found no significant difference between the two approaches ($p < 0.05$). As an outcome, their results suggest that the IPAQ could be used to evaluate PA in individuals with type 2 diabetes (18). Our results are not in concordance with previous studies, being without statistical significance.

In a study published in 2019 (19), the authors found limited concordance among self-reporting adherence to physical activity in the clinical context and IPAQ interviews in individuals with high blood pressure. Furthermore, the authors pointed out that the physical activity suggestion has a low correlation with blood pressure control in the clinical situation, implying that physician advice alone is insufficient to transmit the benefit of supervised physical activity that is proven in the clinical trials to clinical practice. Bravo *et al.* (20) found that self-reported physical activity using IPAQ was mostly related to domestic ($p = 0.018$) and work activities ($p = 0.001$) at moderate intensity in sedentary hypertensive females.

CONCLUSIONS

Within a cardiac rehabilitation program, IPAQ-L can be used to assess individual physical activity levels. IPAQ-L is an inexpensive tool for measuring physical activity in order to produce public health policy proposals or to improve treatment strategies. Health care services are currently under a lot of strain because of the present pandemic situation. The IPAQ-L has reasonable measurement properties for suggesting it as an instrument for national monitoring.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest, and they received no specific funding regarding this scientific research.

BURNOUT AND PSYCHOLOGICAL REACTIVITY TO STRESS OF MEDICAL STAFF IN THE CONTEXT OF THE COVID-19 PANDEMIC (Abstract). The new pandemic context increases the mental reactivity to stress of health representatives by summing up the conditions of overwork, measures to prevent the spread of COVID-19 and excessive media coverage. **Aim**: To monitor the frequency of manifestation of mental symptoms of stress in medical staff, during the COVID-19 pandemic. **Material and methods**: The prospective study, from which we present preliminary data, was conducted on a group of 147 subjects, medical staff and support staff from COVID and non-COVID hospitals, who gave their free consent to answer questions referring to the development of reactive symptoms caused by the COVID-19 pandemic. The questionnaire used was adapted, with the author's consent, from the original published in 1993 in "In the Tiger's Mouth: An Empowerment Guide for Social Action", specifically intended to investigate the burnout syndrome. **Results**: The most frequently to answer were nurses (42.2%) and the resident doctors (29.3%). Moderate psychological impairment was the most frequent symptom (57.1%) and was more frequently mentioned by subjects from non-COVID hospitals (> 50%, p = 0.046). Severe impairment of mental function was more frequently mentioned by subjects from hospitals with COVID profile (40.7%). **Conclusions**: The results of this study confirm the prognostic value of psychological stress symptoms in the onset of the burnout syndrome. The current pandemic context favors a different reaction to stress, especially on medical staff exposed to multiple consumptive factors. **Keywords**: BURNOUT SYNDROME, PSYCHOLOGICAL STRESS SYMPTOMS, MEDICAL STAFF.

The burnout syndrome has been a problem of global interest in work fields for a long time. In 2016, Maslach and Leiter defined it as a delayed response to interpersonal stressors at work. The three dimensions subsidiary to stress reactivity were considered to be exhaustion, cynicism and inefficiency at work (1).

There are a multitude of variables associated with burnout in medical staff. The pandemic context overlaps with them, becoming a factor in increasing the level of a priori stress.

As of January 25, 2020, in the new pandemic COVID-19 context, more than forty thousand medical staff from other provinces have been deployed in Hubei Province in an attempt to prevent an increase in the

number of fatal consequences. At the same time, medical personnel from all over China have begun to fight this highly infectious disease.

However, at that time, anticipations of possible psychological disorders in the context of the growing epidemic and uncertainty about the lack of medical supplies, especially personal protective equipment, were premature (2).

In that point of solidarity, were recorded the first concrete stressors of the epidemic, predictors of worldwide psychological devastation, especially among those working in the medical field: fear of infection and feelings of insecurity, maintained by the widespread media broadcasting (3).

A multicenter survey investigating psychological disorders in medical staff working in different positions showed statistically significant differences between groups, finding a significant increase in total scores for anxiety, depression, sleep quality and stress in participants at high risk of COVID-19 exposure ($p < 0.05$). Subsequent post-hoc analysis indicated that medical staff sent to Hubei had higher scores of anxieties, depression, sleep quality and stress (adjusted $p < 0.05$). The combined prevalence of anxiety, depression and insomnia, for these medical workers, reached 38% (3).

The burnout syndrome is defined, in the narrowest sense, as an accumulation of fatigue over long periods of time, with decreased motivation, interest and productivity at work. It is currently being studied in close connection with predictability with stressors such as those mentioned for the current pandemic context (fear of infection, feeling insecure about protective equipment), but also with the frequency of mental states such as anxiety, depression, insomnia or exhaustion (4, 5).

Psychological interventions are recommended in the early stages of burnout. Their advantages are the improvement in quality of personal and professional life. The disadvantages are the worsening of symptoms, the onset of burnout and decreased efficiency at the work (6). Recommendations for the support of medical staff during the pandemic are theorized, through interventions both in the personal sphere and at the level of the health system. Most studies focus on psychological support (7, 8, 9). Individual resilience, however, plays a key role in managing stress reactivity (9).

MATERIAL AND METHODS

We present a prospective study that began in January 2021, from which we highlight the preliminary data on a group consisting of 147 subjects, medical staff and support staff from several COVID-19 and non-COVID-19 hospitals from Iasi, Romania, who gave their free consent to answer questions regarding the occurrence of reactive symptoms caused by the COVID-19 pandemic.

The questionnaire we used was adapted, with the author's consent, after the one published in 1993 in "In the Tiger's Mouth: An Empowerment Guide for Social Action" by Katrina Shields, intended to investigate the burnout syndrome. The distribution of the questionnaires was initiated after acquiring the acceptance of the Ethics Commission. Completion of the questionnaires was done after obtaining the informed consent of all participants. In processing the reactions, the principle of scores was used, applied individually, but which varied by framing the answers in a qualitative value, designated by reference to the percentiles. We will present the results of the psycho-

logical manifestations within the burnout syndrome on the studied cases.

Data were collected by a team of physicians and analyzed using *SPSS 18.0* software. The ANOVA test, the F test $_{(ANOVA)}$, the multivariate analysis, the ROC curve, the χ^2 test and the t-Student test, the Kruskall-Wallis and Pearson correlation were applied in the quantitative interpretation of the data. Statistical significance was defined in the 95% confidence interval ($p < 0.05$).

RESULTS

Depending on the occupation of the respondents, most frequently answered: nurses (42.2%), representing 45.9% of the staff working in hospitals and the resident doctors (29.3%), 27.9% of the staff working in hospitals (fig.1, tab. I).

TABLE I

Lot structure according to occupation

Occupation	Hospital (n=122)	Ambulatory (n=25)	Total (n=147)
Specialist / Senior physician	13 (10.7%)	10 (40.0%)	23 (15.6%)
Resident physician	34 (27.9%)	9 (36.0%)	43 (29.3%)
Nurse	56 (45.9%)	6 (24.0%)	62 (42.2%)
Other staff	7 (5.7%)	-	7 (4.8%)
Orderly	12 (9.8%)	-	12 (8.2%)

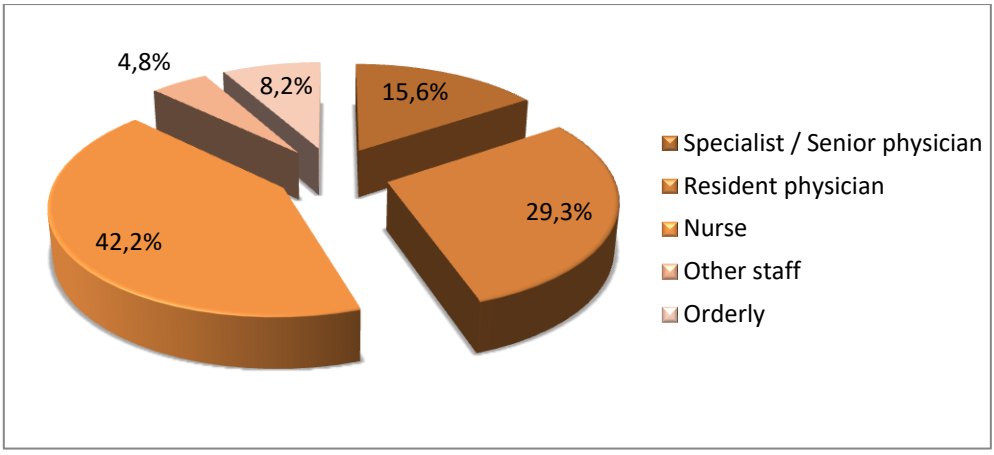

Fig. 1. Distribution of subjects according to occupation

Some of the items provided significant results:

Item 5. *Do you feel tired because your sleep is:*

- insufficient sleep - was reported "often" (26.5%) and "very often" (16.3%) by about 50% of the subjects;

- restless sleep, more frequently found as "sometimes" in 32.7% of subjects;

- sleep full of nightmares was noticed in about 25% of the subjects (27.8%), "often" only 5.4% and "very often" 2%.

Item 6. *Do you feel more:*

Emotional impairment showed the fol-

lowing percentage distributions (fig.3):

- irritability was reported "often" (17%) and "very often" (10.2%) by approximately 50% of the subjects;

- anxiety was more frequently reported by 38.8% of the subjects, "often" and "very often" being noticed in 21.1% of the subjects;

- emotional instability was "often" noticed only in 7.5% of the subjects and "very often" in 4.8%, but 51% of the respondents did not declare this manifestation.

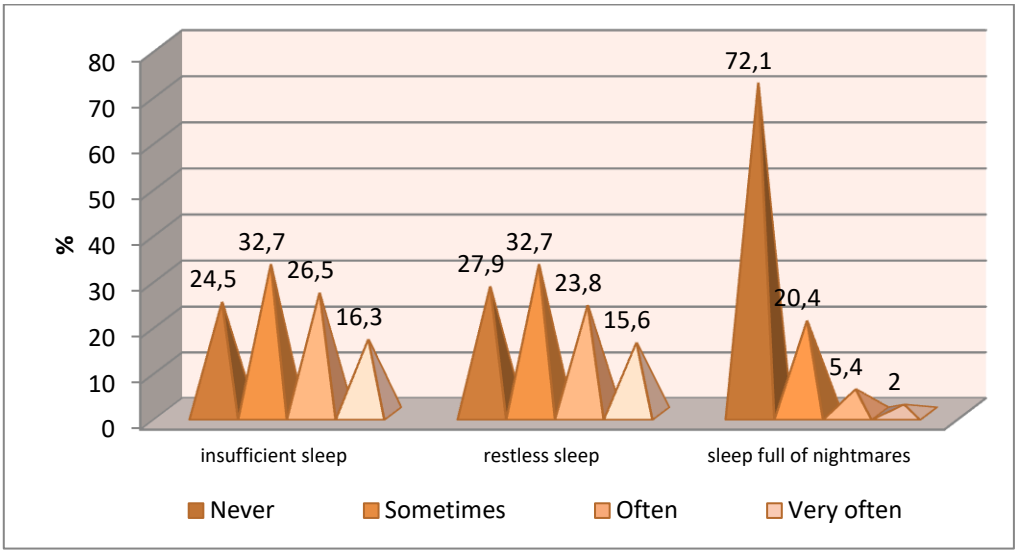

Fig. 2. Results to item 5 *"Do you feel tired because your sleep **is**"*

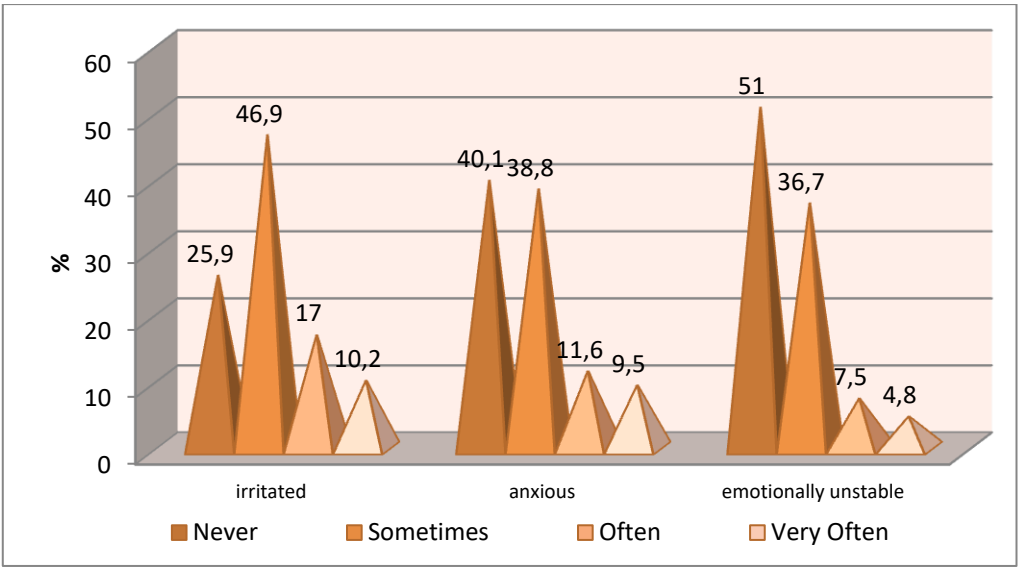

Fig. 3. Results to Item 6 "*Do you feel emotionally affected*"

Item 7. *Are you afraid of:*

The fear of infection did not exist in 36.1% of the subjects, but 46.3% of the respondents sometimes had this fear. Fear of infection was "often" and "very often" reported by 17.7% of subjects. The share of cases according to the fear of transmitting the disease to others was relatively balanced among respondents: 25.2% never had this fear, but 27.2% answered "often" (fig. 4).

Item 8. *Do you feel lately that coming to work no longer pleases you?*

The discomfort of going to work was declared "often" (12.9%) and "very often" (17%) by about one third of the subjects, but 42.2% of the respondents still had the pleasure of going to work (fig. 5).

Item 9. *Do you feel more:*

Less than 10% of the subjects stated that in the last period they were "very often" sad (9.5%), lacking the desire to communicate (6.1%) and lacking optimism (8.2%) (fig. 6).

Item 10. *Since the onset of the COVID pandemic, have you feel like drinking alcohol?*

Alcohol consumption during the pandemic was reduced: "often" (1.4%) and "very often" (2.7%), and 78.9% of respondents did not change their behavior (fig. 7).

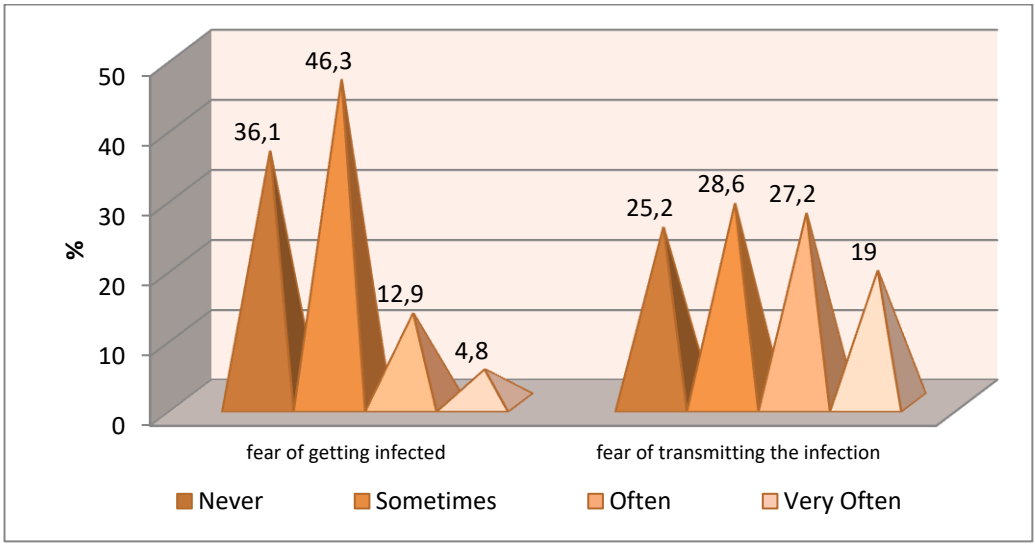

Fig. 4. Results to Item 7 *"Do you have fears"*

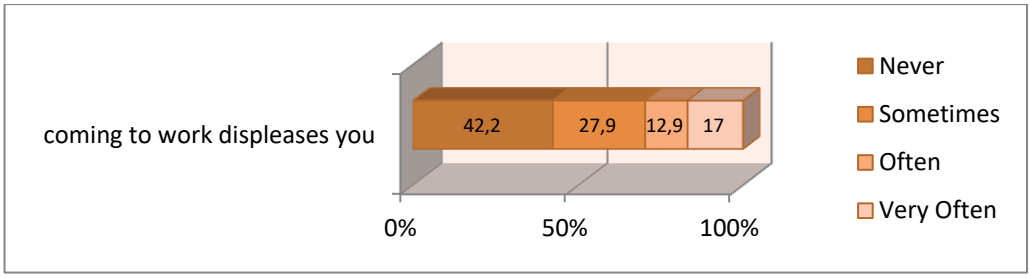

Fig. 5. Results to Item 8 *"Do you feel lately that coming to work no longer pleases you"*

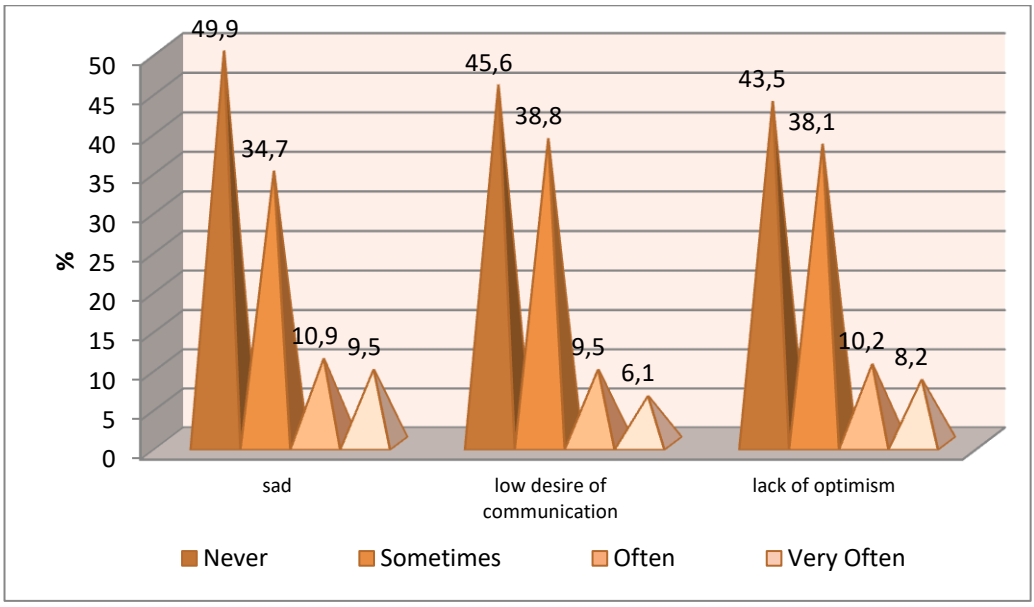

Fig. 6. Results to Item 9 *"Do you feel emotionally affected"*

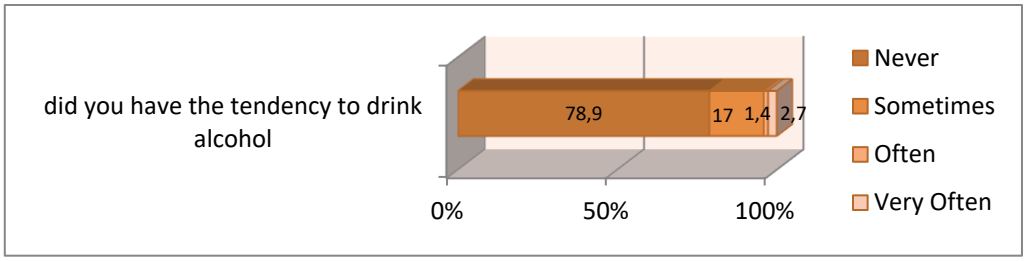

Fig. 7. Results to Item 10 *"Did you have the tendency to alcohol consumption"*

Item 11. *Recovery measures*

The proposed recovery measures showed the following percentage distributions (fig. 8):

- more free time was mentioned "often" (33.3%) and "very often" (23.1%) by about 50% of the subjects;

- qualified help at work (psychotherapy) was "often" and "very often" requested by 25.1% of the subjects, but not mentioned by 46.9% of the subjects

- financial supplementation, as a recovery measure, was mentioned "often" (28.6%) and "very often" (29.3%), but 17% of respondents did not state this solution.

Within the studied groups, a share of 57.1% of subjects with moderate, 19.7% mild and 23.1% with severe impairment of psychological manifestations was noticed (fig. 9).

Specialist and senior physicians (73.9%), resident physicians (62.8%) and nurses (56.5%) more frequently mentioned moderate mental impairment, while 57.1% of the other staff more frequently mentioned mild mental impairment, and 50% of nurses, severe impairment ($p = 0.05$) (fig. 10).

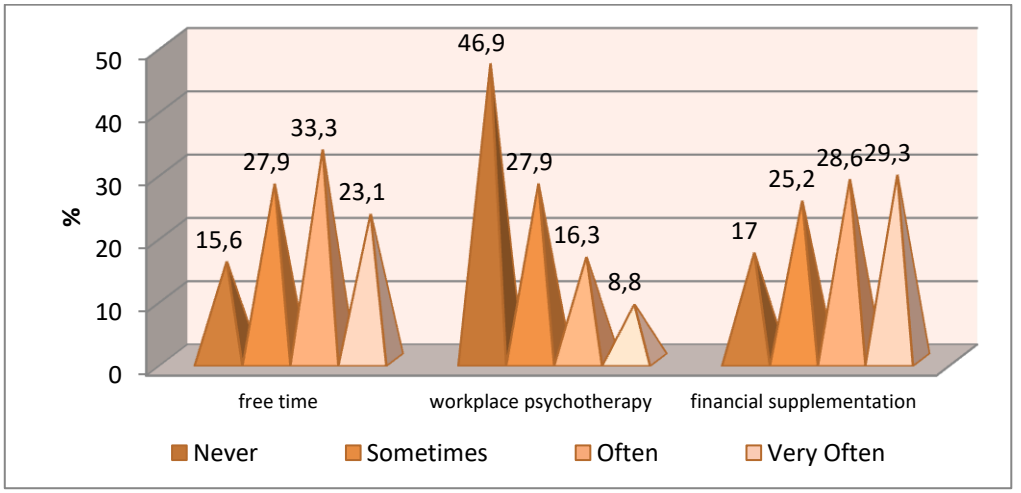

Fig. 8. Results to Item 11 *"Recovery measures"*

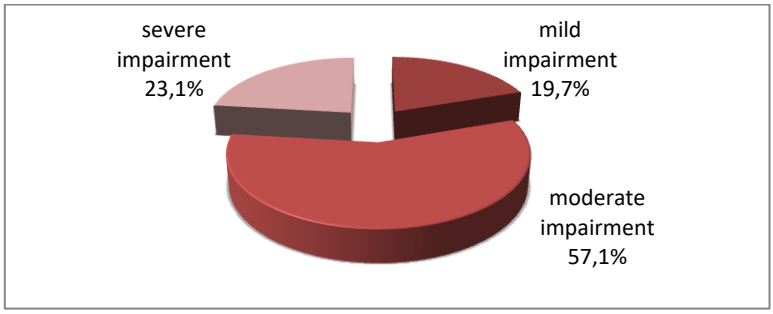

Fig. 9. Distribution of cases according to the overall score for psychological manifestations

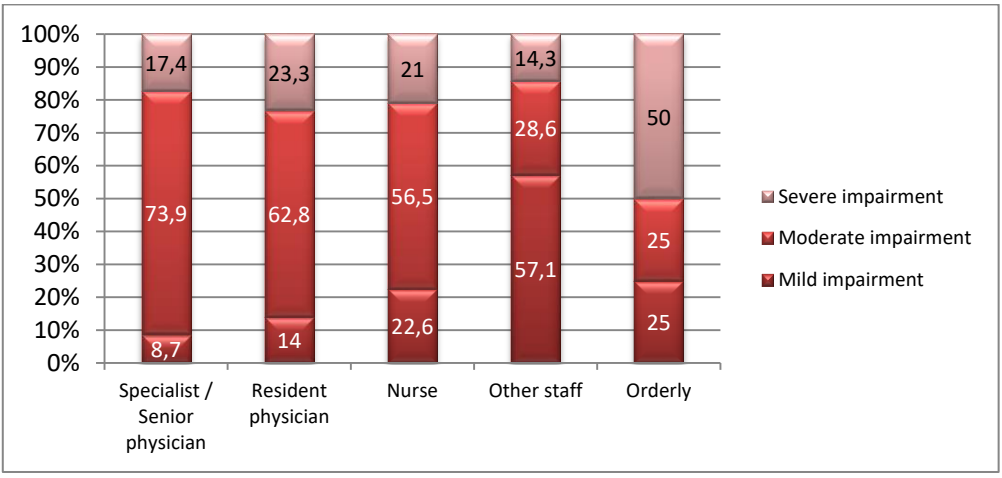

Fig. 10. Distribution of cases according to occupation and overall score for psychological manifestations

The gender distribution of the overall score for mental manifestations showed moderate impairment in both sexes: 69.6% of men and 54.8% of women, but the slightly higher frequency of severe impairment in women should be noted (8.7% *vs.* 25 .8%; p = 0.146) (fig. 11).

Both in the age group under 40 and in those over 40, the degree of mental impairment was moderate (56.3% vs 58.8%; p = 0.741) (fig. 11).

In patients from urban areas, but especially in those from rural areas, the degree of mental impairment was moderate (48.6% *vs.* 85.7%; p = 0.033) (fig. 11).

The distribution of scores for psychological manifestations according to marital status showed moderate impairment in both categories: 63.6% of subjects without a partner (unmarried, divorced, widowed) and 55.8% of subjects with a partner, but the percentage differences were not significant from a statistical point of view (p = 0.174) (fig. 11).

It should be noted that about 1/4 of the subjects had severe mental manifestations, with the exception of males and patients from rural areas.

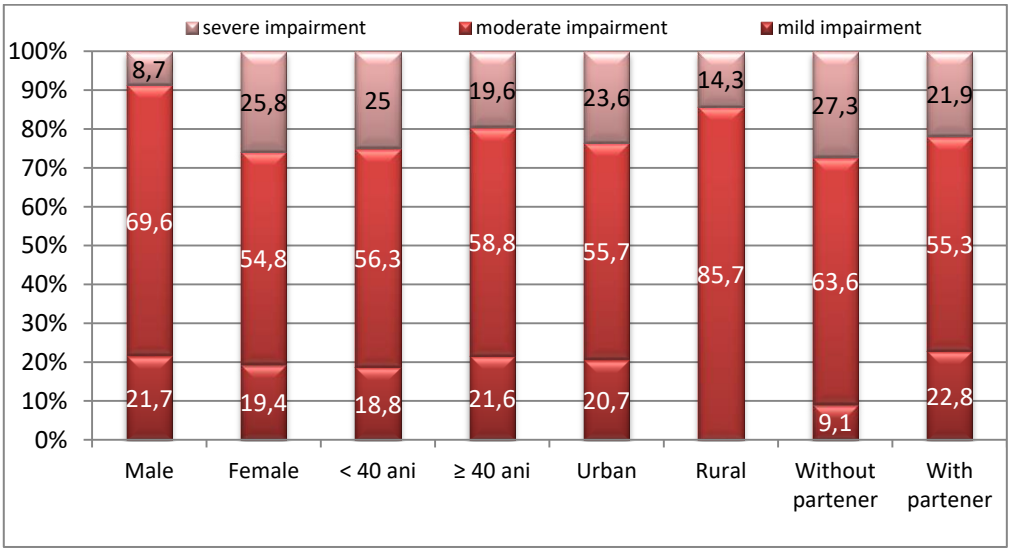

Fig.12. Distribution of cases by gender, age groups, background and marital status according to the overall score for mental manifestations

DISCUSSION

According to our results, over half of the subjects expressed fear of becoming infected and transmitting the disease. The current literature confirms this. The prevalence of psychosomatic and psychological symptoms recorded in medical personnel during the COVID-19 pandemic was predominantly represented by the fear of transmitting the infection to their families and contracting the disease (7, 10, 11).

Fear of infection was also associated with the scores of exhaustions, depression, anxiety, and stress (p <0.05), and physicians and nurses working in direct contact with infected patients recorded increased levels of exhaustion, depression, stress at work and lack of job satisfaction, compared

to those least exposed (12, 13, 14).

The rate of depression is higher in those with a higher degree of exposure to the disease, both during the COVID-19 pandemic and during the SARS pandemic (6, 15, 16). Our data are statistically significant from this point of view, as the participants from hospitals with COVID profile were the majority in terms of severity of psychological symptoms, compared to the non-COVID medical units.

According to our results, 1/3 of the respondents said they lost the satisfaction of going to work. All medical staff (treating physicians, resident physicians, nurses) suffer from the impact of following new circuits, being subjected to a limited range of interaction with patients and the brevity of the anamnestic and clinical examination, sometimes with the risk of truncating fundamental elements. In addition, the stress of the program and the modified shifts, the prolonged wearing of equipment and protective masks, lack of food, hydration and rest were acutely experienced. The stress that occurs during the equipment undressing process, whose strict protocol ensures the chance of effective protection, but in which a minimal error can be a circumstance of individual infection and or of those around (13, 14, 17) was also frequently reported.

According to our results, the psychological impairment in the context of stress reactivity was moderate in over half of the doctors and nurses, being mild in other staff. The most severely affected were hospital attendants, in a statistically significant proportion. The literature shows a tendency to severe mental symptoms in nurses, by comparison them being more affected than doctors (18, 19, 20).

Regarding the ways of recovery proposed by the subjects, financial supplementation and free hours registered the highest rate.

There are current directions regarding how to prevent the burnout syndrome, including the optimization of the staff schedule, the number of patients taken over by each, the improvement of protective equipment and operating circuits, the assurance of special transport and accommodation when necessary (21, 22, 23). An online education and counselling platform for medical staff (Battle Buddy), with an interest in specific steps for launching psychological resilience interventions (24, 25, 26) are also considered.

CONCLUSIONS

Our data show that the predictors of severe mental manifestations of burnout are fear of infection, fear of transmitting the disease and insufficient sleep. The overall score of mental manifestations showed a moderate mental impairment in over half of the participants; the severity of mental symptoms is predominant in those most exposed to the disease, especially in nurses and medical assistants.

The assessment of psychological symptoms in the case of burnout must be related to all dimensions of the social life, including contemporary values, economic aspects, geographical area and cultural characteristics, independent of the pandemic crisis, as the initial psychological background can determine how to respond to the crisis.

There are substantial overlaps between the clinical samples of burnout and non-burnout patients. The use of screening tools without a rigorous medical history also creates the risk of both false positive and negative results.

Current issues of particular relevance to the medical world include the possible links between the burnout syndrome and mental illnesses, with differential diagnosis being necessary and difficult to perform in certain clinical circumstances.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest, and they received no specific funding regarding this scientific research.

NEWS

UVC LIGHT EFFICIENTLY KILLS SARS-COV-2

A direct approach to limit airborne viral transmissions is to inactivate them within a short time of their production. Far-UVC light (207-222 nm) efficiently kills pathogens potentially without harm to exposed human tissues. As all human coronaviruses have similar genomic sizes, far-UVC light would be expected to show similar inactivation efficiency against other human coronaviruses including SARS-CoV-2. Continuous far-UVC exposure in occupied public locations at the current regulatory exposure limit would result in viral inactivation. Low-dose-rate far-UVC exposure can potentially safely provide a major reduction in the ambient level of airborne coronaviruses in occupied public locations. Thus far-UVC light potentially has about the same highly effective germicidal properties of UV light, but without the associated human health risks. (Buonanno M, Welch D, Shuryak I *et al.* Far-UVC light (222 nm) efficiently and safely inactivates airborne human coronaviruses. *Sci Rep* 2020; 10: 10285).

PALLIATIVE CARE IN NEOPLASTIC PATIENTS WITH *CLOSTRIDIOIDES DIFFICILE* ASSOCIATED INFECTION - THE EXPERIENCE OF A UNIVERSITY HOSPITAL FROM NORTH-EAST ROMANIA

PALLIATIVE CARE IN NEOPLASTIC PATIENTS WITH *CLOSTRIDIOIDES DIFFICILE* ASSOCIATED INFECTION - THE EXPERIENCE OF A UNIVERSITY HOSPITAL FROM NORTHEAST ROMANIA (Abstract): *Clostridioides difficile* infection (CDI) has become an important public health problem over the last decade, especially in developed countries. Both the incidence of infection and the severe forms recorded significant increase. At the same time, *Clostridioides difficile* is the main cause of diarrhea associated with medical care and, in particular, antibiotic use. The **aim** of this study was to measure the impact of CDI on neoplasic patients. **Material and methods:** We have quantified in this prospective observational study symptoms, the effects of hospitalism and antibiotic use at 132 patients diagnosed with *Clostridioides difficile* infection in "Sf. Parascheva" Infectious Diseases Clinical Hospital, between 2017-2019. **Results:** Most of the patients experienced delays in diagnosis and treatment; almost 35% waited 6-21 days and 15% over 21 days. The delayed diagnosis brought further complications; 65% did not experience symptom resolution within seven days after initiating the treatment. We have noticed that after CDI, patients' priorities have changed; they started to be more concerned about the healthcare system, particularly time to diagnosis and treatment, antibiotic usage, alimentation and needs from a healthcare provider. **Conclusions:** The main issues are the management of symptoms and the need to use strategies that will allow the patients to control their illness and treatment better. **Keywords:** PALLIATIVE MEDICINE, QUALITY OF LIFE, MULTIDISCIPLINARY APPROACH, NEOPLASTIC PATIENT, CARE PREVENTION.

Clostridioides difficile infection (CDI) is an important public health problem worldwide, associated with significant morbidity and mortality, correlated with antibiotic use, and prolonged hospitalizations (1-5). *Clostridioides difficile* is a Gram-positive anaerobic, sporulated bacillus of the order *Clostridiales*, family *Peptostreptococcaceae*, genus *Clostridioides*, first described in 1935, recognized in 1978 as the etiological agent of pseudomembranous colitis (6). It's found in humans, animal feces, water, and soils. Pathogenic strains produce multiple toxins (7), the most common are enterotoxin (*Clostridioides difficile* toxin A) and cytotoxin (*Clos-*

tridioides difficile toxin B). Both toxins may produce diarrhea and inflammation in infected patients. It's responsible for 15-25% of cases of post-antibiotic diarrhea and all cases of pseudomembranous colitis (8, 9).

Clostridium difficile is a major emerging human pathogen found in the human colon without causing disease (10). Several risk factors are involved in the development of CDI, including admission to healthcare facilities, comorbidities, advanced age, and exposure to antibacterial agents (11). Studies indicate that *C. difficile* is normally present in 2-5% of the adult population; (12) colonization is frequently associated with a history of unrelated diarrheal diseases, such as food poisoning or laxative abuse. (13) It is the main cause of hospital-acquired infectious diarrhea in adults, with rising infection rates since 1999 (14, 15). People with no history of gastrointestinal symptoms are unlikely to become asymptomatic carriers. These individuals are a major reservoir of infection. (16) Disruption of host-microbiota, most commonly by antibiotic treatment, increases susceptibility to infection. (17,18) Almost 20% of adults over the age of 65 are asymptomatically colonized by *Clostridioides difficile*, which increases the chance of CDI and can be a source of transmission in a medical facility (19,20)

Clinically, CDI ranges from uncomplicated diarrhea to fulminant and sometimes fatal, pseudomembranous colitis (associated with severe inflammation of the colon and the formation of pseudomembranous on the surface of the intestinal mucosal) (12).

The estimated all-cause 30-day mortality rate among patients who acquire CDI in healthcare facilities is 3-30% (21, 22).

MATERIAL AND METHODS

This prospective observational study is performed in the "Sf. Parascheva" Hospital of Infectious Diseases Iasi, Romania. The recruitment period was three years, 2017, 2018, 2019. The patients were selected using following criteria: adult (age > 18 years old), history of neoplasia, patients presenting bacteriological evidence of CDI during hospitalization, after giving informed consent.

The exclusion criteria were patients involved in an ongoing study, patients who could not fill out a questionnaire for any cognitive reasons, and the patients with chronic inflammatory bowel disease.

All relevant clinical data were collected from the patient's records: gender, age, comorbidity, symptoms, length of stay, ICU (Intensive Care Unit) hospitalization, immunosuppression, presence of any CDI episode within the previous 2-year period, treatment, outcome. Informed consent was obtained from all subjects involved in the study.

RESULTS

A total of 132 patients were included. Four patients died during hospital stay (for causes other than CDI) after completing the survey, and their data were included in the analysis.

The ages were between 30 and 99 years old with a median of 64.5 years, 38.64% were female, and 61.36% were men. The majority (78.05%) were between 50 and 79 years old (tab. I).

The CDI was coded as primary diagnosis in 89% of cases indicating that it was

the reason for admission to the hospital. The four most frequent primary diagnoses were sepsis, urinary infection, endocarditis, and viral encephalitis.

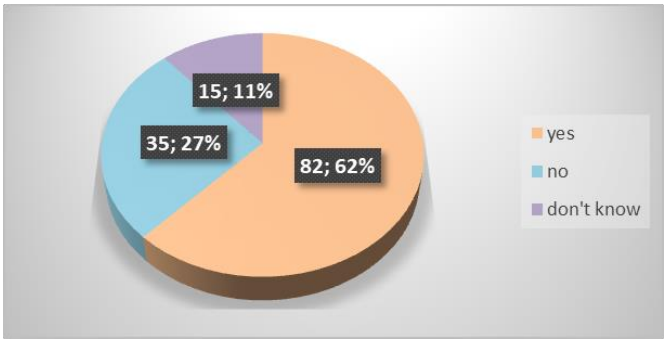

Fig. 1. Distribution of patients that took antibiotics before diagnosis.

TABLE I.
The patients distribution by gender and age.

Gender	N	%
Female	51	38.64
Male	81	61.36
Age (yo)	N	%
18-29	0	0
30-39	3	2.27
40-49	6	4.54
50-59	18	13.66
60-69	45	34.09
70-79	40	30.3
80-89	18	13.63
90-99	2	1.51
Median age	60-69	

CDI has been most commonly correlated with exposure to antibiotics and prior hospitalization for non-CDI-related reasons. Almost 62% of the patients indicated taking antibiotics three months before being diagnosed (fig. 1). Of these, 20.45% had colon cancer, 13.63% pulmonary cancer, 12.87% prostate cancer, 12.87% liver cancer (fig. 2).

Almost 38% indicated their symptoms began in the hospital, 31% indicated that the symptoms started in the first six days of admission, 25% indicated 1-2 weeks, 26% indicated 3-4 weeks, and 18% reported between 6 weeks and six months (fig. 3).

Almost 61% of the patients indicated that their symptoms began within hospitalization. Only 10% indicated they were at home when the symptoms started, and 24% indicated living in a long-term care home (fig. 4).

CDI can be a severe infection, especially in immunosuppressed patients. The most common symptoms were watery severe diarrhea (72%), common diarrhea (65%), fatigue (68%), loss of appetite (59%), and

weight loss (53%) (fig. 5). Most respondents experienced two or more symptoms, with the majority reporting between four and seven.

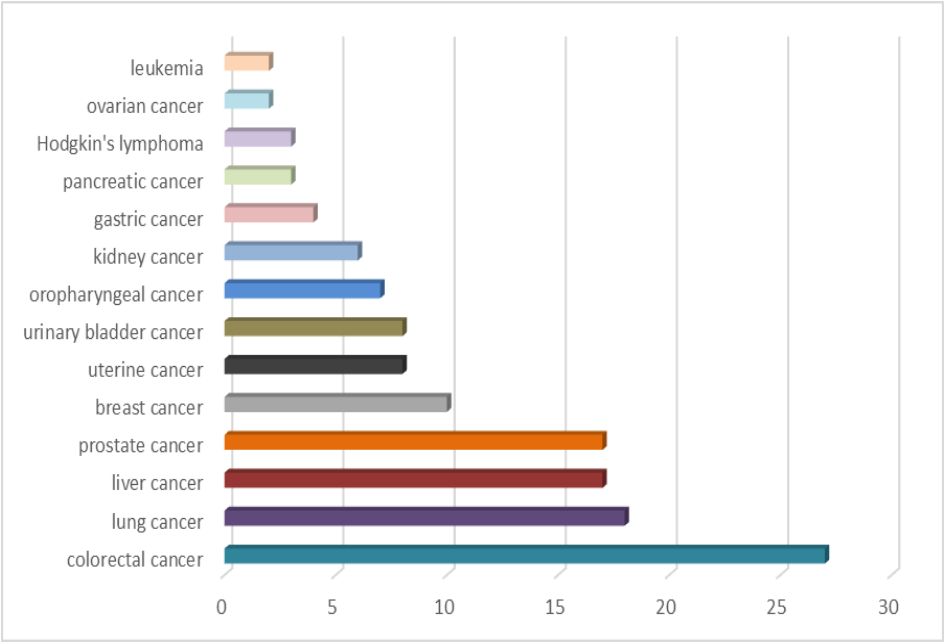

Fig. 2. Distribution of patients according to their history conditions.

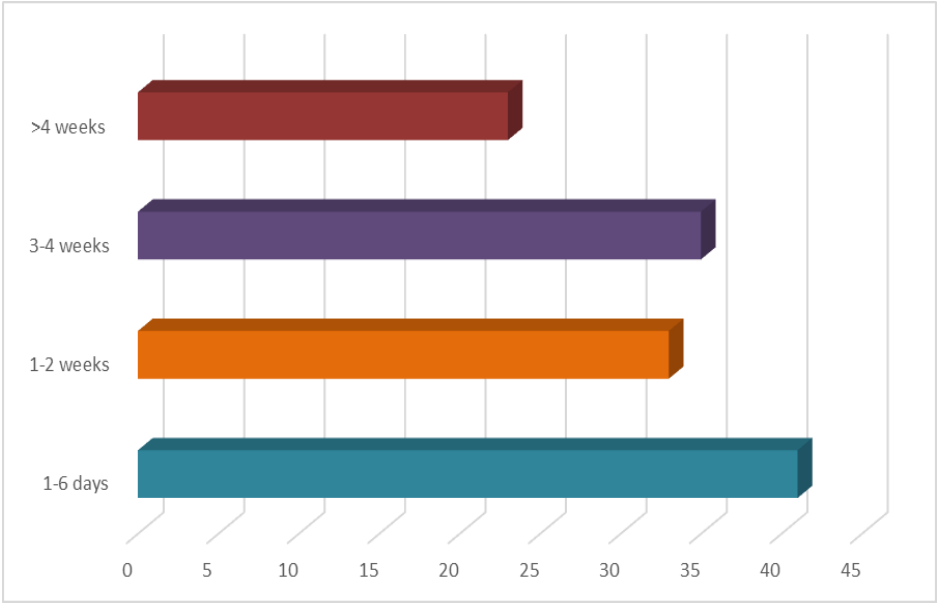

Fig. 3. Development of first symptoms.

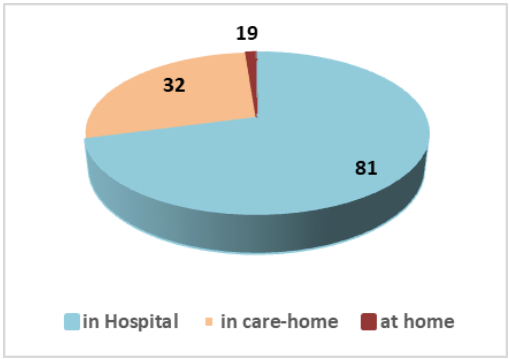

Fig. 4. Exposure to health-care facilities preceding the development of first symptoms.

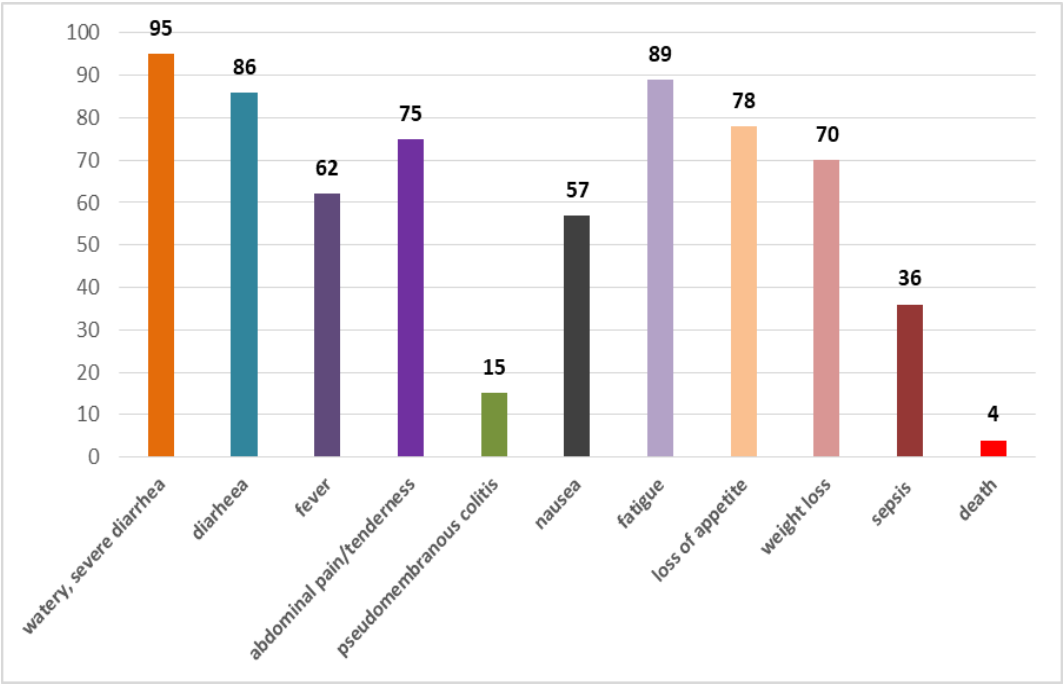

Fig. 5. Symptoms of the patients.

The recurrence rate of CDI was between 27%, 46 patients indicated having CDI more than once, and 20 could not remember. Of the respondents who had CDI more than once, 38 experienced CDI two to four times, while 9 experienced CDI five or more times (fig. 6).

To have therapeutic success for CDI, time to diagnosis is critical. Only 17% of respondents received their diagnosis within the first 48 hrs after the onset of their symptoms, 28% had their diagnosis established between 2 and 5 days, and 30% between 6 and 30 days.

The treatment was established according to the national and international protocols; 35% of the patients indicated that their symptoms resolved within seven days,

29% experienced resolution between 8 to 14 days, 25% were treated for longer than 14 days, and 10% did not experience resolution.

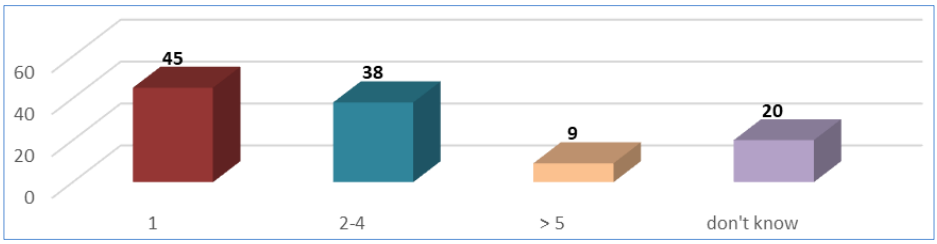

Fig. 6. Number of reinfections.

If antibiotic therapy is inefficient, fecal microbial transplantation (FMT) is reported to be a safe and effective alternative. A total of 3 patients out of 67 who had experienced subsequent CDI indicated treatment by FMT. The three patients who received FMT were treated previously with the complete scheme of antibiotics.

CDI can significantly impact patient's lives, especially on patients with cancer. We were interested in how this infection affects their quality of life (QoL). Our hospital psychologists did a three-question survey with scores ranging from 5 (being able to have a normal activity at home and work with no restrictions) to 1 (unable to take care of themselves and needs institutional or hospital care). Almost 25% of the patients reported that they could not take care of themselves, 35% were unable to work and needed assistance with everyday activities, 37% could have a regular activity at work and home. We observed that someone who experienced a reduced QoL before CDI experienced a more severe impact on their quality of life during active diseases.

Also, we were interested in the long-term impact of CDI on the lives of patients with neoplasia. We asked some participants about their current quality of life. The answers weren't very conclusive because the patients answered in different stages after recovering. Patients at their fourth, fifth reinfection reported QoL at a low level; many suffer from long-term consequences. Some of the patients are afraid of returning in collectivity and to eat regular food without testing every aliment, avoid taking certain medications such as antibiotics, and increase the use of probiotic supplements.

Patients changed preventive behaviors due to having RCDI. More than 40% said that they significantly increased their handwashing, 45% increased their house cleaning, use of bleach, antibacterial wipes, and gels compared to their behavior before being ill. Some avoided public places such as public bathrooms and going to restaurants.

DISCUSSION

Patients who contract CDI often experience painful, embarrassing, and debilitating symptoms, confirmed by our survey of patients with prior RCDI. Diarrhea, abdominal pain, and exhaustion were most likely to be rated as severe, whereas the presence and severity of other symptoms such as fever and headache were more

variable. Almost 39% of the respondents estimated that they could not perform routine daily activities because CDI varied considerably.

Increased hand washing and the use of soap and water for cleaning are evidence-based strategies demonstrated to reduce the acquiring and transmitting infections significantly (23).

Respondents who said they eat out less or avoid public places may impact their quality of life without changing their risk of future illness. Physicians should discuss these behaviors with their patients and assure them that they can still do their everyday activities with appropriate preventive behaviors, such as handwashing (24, 25).

In our cohort, almost 52% of our patients with RCDI were not concerned about avoiding certain medications. Medical literature has shown that proton pump inhibitors (PPIs) increase CDI risk, incident cases, and recurrences (26). Antibiotics also increase CDI risk. The risk is even greater when they are combined with a PPI (27, 28).

Physicians should consider the indications for antibiotic use and PPIs in patients with RCDI. They should empower patients to discuss the risks of RCDI and the benefits of antibiotic treatment; they should encourage their patients to ask about future antibiotic use. Healthcare providers should remind patients to consult with a specialist before stopping a medication because the risks outweigh the benefits (29).

More than 31% of respondents reported increasing their use of probiotics following CDI. Probiotics are microorganism-based products that have been proposed as a therapy to reconstitute disturbed gut microflora due to antibiotic use. The use of probiotics to prevent CDI is still controversial (29, 30).

Individuals currently treated for CDI or with a history but no current treatment for CDI have significantly worse QoL, more significant impairment in their daily activities, and reduced work productivity than those with no history of CDI (31).

The study demonstrates a significant impact of CDI on patients' self-assessed quality of life and the lasting impact that CDI has on patients with cancer, highlighting the importance of early diagnosis and immediate initiation of the treatment.

Nowadays, palliative care is a growing specialization that meets with dignity the needs of the patient with serious illness; this specialty aimed to provide end of life care for patients with advanced cancer and their families, focusing on relieving the pain, controlling the symptoms, and improving the quality of care for patients and their families (32). In our study, the patients with a low quality of life need palliative care assistance.

CONCLUSIONS

This study revealed that cancer patients with CDI experience many overwhelming symptoms which affect their QoL. Different therapeutic options are now available, and new treatments are currently in development to define the best strategies for managing this infection at the first episode and in case of further recurrences. All health professionals must ensure that patients receive appropriate prevention guidance and care. It's compulsory to develop measures for effective management of symptoms in order to improve the QoL.

Reducing infection rate and the spread of CD could benefit the patient's life and reduce the cost of CDI treatment and hospi-

talization. The multidisciplinary approach represents the key to success in the clinical management of CDI neoplastic patients.

NEWS

THE USE OF IVERMECTIN FOR COVID-19 IN PREGNANCY

Ivermectin, an antiparasitic agent used to treat parasitic infestations, inhibits the replication of viruses in vitro. The molecular hypothesis of ivermectin's antiviral mode of action suggests an inhibitory effect on severe acute respiratory syndrome coronavirus. Besides the lack of adequate clinical safety of ivermectin in human pregnancies, an additional risk factor to these women would be the coadministration of a P-glycoprotein inhibitor (e.g., clarithromycin, cyclosporin, diltiazem, erythromycin, felodipine, omeprazole, tamoxifen, and some statins to name a few). Studies conducted on mice have shown increased systemic exposure, organ concentrations, or toxicity of ivermectin, and that this combination will likely cause an increased level of ivermectin in the developing embryo or fetus, potentially inducing birth defects (Wise LD, Scialli AR. Ivermectin for COVID-19: Concerns during pregnancy. *Reprod Toxicol*. 2022; 107: 43 / doi: 10.1016/j.reprotox.2021.11.005).

DIETARY PATTERNS IN ROMANIAN PATIENTS WITH TYPE 2 DIABETES MELLITUS

DIETARY PATTERNS IN ROMANIAN PATIENTS WITH TYPE 2 DIABETES MELLITUS (Abstract): Adherence to healthy dietary patterns leads to improvements in metabolic health and prevents the risk of diabetes and obesity. Current guidelines underscore the importance of focusing on individualized dietary patterns in nutritional therapy of diabetics. The objectives of this study were to identify the dietary patterns in Romanian patients with Type 2 Diabetes Mellitus and to investigate the impact of these dietary patterns on associated anthropometric and metabolic parameters. **Material and methods**: A total of 118 adults were included in this cross-sectional, observational study. Demographic and lifestyle data, information on current pathologies and associated co-morbidities, anthropometric measurements and biological markers were obtained. Dietary intake was assessed via the EPIC food frequency questionnaire. **Results:** We identified three dietary patterns by principal component analysis, defined as *Prudent*, *Western* and *Traditional*. We found that patients belonging to the Western pattern had higher waist-to-hip ratio, higher glycated hemoglobin A1c and were significantly younger compared to those in the Prudent pattern. Alcohol intake was significantly higher in the *Western* compared to the *Prudent* pattern. **Conclusions:** This study demonstrates that the *Western* pattern, characterized by high intake of meat and meat products, eggs and soft drinks, has negative metabolic consequences in Romanian adult patients with T2DM, compared to the *Prudent* pattern. The *Traditional* pattern was closer to the *Prudent* one. **Keywords:** TYPE 2 DIABETES MELLITUS, DIET, DIETARY PATTERN, FOOD FREQUENCY QUESTIONNAIRE, NUTRIENTS.

Type 2 Diabetes Mellitus (T2DM) is a major and complex chronic disease and a worldwide public health issue. The epidemic of T2DM parallels the epidemic of obesity and the adoption of an unhealthy sedentary lifestyle. Epidemiological evidence demonstrates an unprecedented increase in the prevalence of diabetes around the world, from 125 million individuals with diabetes in 1990, to 537 million in 2021 and to an estimated 643 million by 2030. Of particular concern is that the increase incidence of diabetes disproportionately affects populations with a low socioeconomic status (1). In Romania, a recent, large epidemiological study has shown that

11.6% of the adult population has diabetes and 16.5% has prediabetes (2). The high prevalence of excess weight in the Romanian population may partly explain the high number of diabetic individuals since 31.1% of the Romanian adult population is overweight and 21.3% is obese (3).Thus, nutritional assessment (anthropometric, biochemical, clinical, dietary) is important to highlight the relationship with chronic diseases. Anthropometric parameters are predictive factors for cardio-metabolic diseases (4), obesity can be associated with certain infections (5) and malnutrition is frequent in surgical patients (6).

Numerous global changes in the modern lifestyle led to unhealthy eating behaviors (7). The most important changes are lack of physical activity and an increased preference for readily available calorie-rich foods with low nutritional value, leading to a shift toward a Western-like food pattern (1). Recent evidence showed that metabolic health is less influenced by each individual nutrient and is more driven by these global dietary patterns and the consumption of specific foods that have synergistic effects (8). For example, a typical Western diet is generally associated with insulin resistance, hyperlipidemia and pro-inflammatory status, thus increasing the risk of T2DM and cardiovascular diseases. On the other hand, a prudent or healthy diet is associated with a low risk of all-cause mortality (9), diabetes and obesity (10). In particular, there is compelling evidence demonstrating that, in individuals with type 2 diabetes, a healthy dietary pattern improves glycemic control and cardiovascular risk factors (11). Thus, current guidelines emphasize the need of medical nutrition therapy in diabetes to focus on dietary patterns and not on the individual components of the diet and should be individualized to the needs of the targeted population (12).

MATERIAL AND METHODS

Study design

A one-year (2017), cross-sectional observational study was conducted on a group of patients with T2DM who were admitted-for the annual medical evaluation at the Center for Diabetes, Nutrition and Metabolic Diseases at "Sf. Spiridon" County-Clinical Emergency Hospital from Iasi, Romania. The study was approved by the Ethics Committee of the "Grigore T. Popa" University of Medicine and Pharmacy Iasi (Registration no 2327/02.02.2017). All patients received information about the study and signed informed consent before any investigation commenced.

Study population

Adult patients (n=118) of which 55 males and 63 females, with an average age of 60.8±10.05 y, with diagnosed T2DM, and on diabetes nutrition therapy with or without oral anti glycemic medication, who provided informed consent were enrolled in this study. Therefore, children, patients with T2DM treated with insulin or GLP-1 receptor agonists, patients with type 1 diabetes mellitus, malnutrition, psychiatric diseases, inflammatory diseases, individuals who were institutionalized or intellectually unfit, or those unwilling to sign the informed consent were excluded from the study.

Data collection

For each patient, socio-demographic and lifestyle data (age, sex, area of residence, smoking status, alcohol intake) and personal medical history including associated co-morbidities were recorded. In addition, anthropometric parameters such as weight, height and waist circumference were taken, using standard methods with a

calibrated scale and stadiometer. Waist circumference (WC) was measured with a tape measure midway between the rib case and the upper edge of the iliac crest, around the abdomen, in a horizontal plane, parallel to the floor, at the end of a normal breath. Normal values were considered <80 cm in women and <94 cm in men, according to the International Diabetes Federation criteria for abdominal obesity (13). Body mass index (BMI) was calculated [Weight (kg) / Height^2 (m^2)] and patients were classified according to the World Health Organization criteria. We also calculated the waist-to-hip ratio (WHR), as the ratio between waist circumference and hip circumference, where normal values are less than 0.85 in women and less than 0.95 in men (14). Blood pressure was measured twice in all patients, using a mercury sphygmomanometer. Fasting blood samples were collected in all patients and the following laboratory tests were performed: plasma glucose, (measured by spectrophotometric method - colorimetric enzyme), glycated hemoglobin (HbA1c) (measured by HPLC assay), total cholesterol, LDL-cholesterol, HDL-cholesterol, triglycerides (all measured by spectrophotometry, enzymatic method), C-reactive protein (measured by latex immunoturbidimetric assay).

Dietary assessment

Food intake (frequency and quantity) was estimated using the translated, adapted and validated version of the EPIC-Norfolk -FFQ (15). Participants were asked to specify the appropriate frequency of intake for each of the listed foods (133 items), choosing from the nine proposed frequency categories, from never before or less than once a month to more than 6 times a day. We used FETA program (16) for food analysis, which generated the daily average energy and nutrients intake and the daily average intake (in grams/day) of the 13 food groups generated in FETA: cereals and derivatives (which includes bread, pasta, polenta), potatoes, meat and derivatives, fish and derivatives, eggs, fruits, vegetables, milk and derivatives, nuts/seeds, sugar/snacks, fats/oil, soups/sauces, soft drinks (which includes all non-alcoholic beverages, sweetened coffee and tea) and, in addition, alcoholic beverages.

Statistical analysis

The applicability of the principal component analysis for the variables used was verified using the Keyser-Meyer Olkin test (KMO) and the Bartlett test. A KMO value of >0.5 was acceptable and a p value of <0.05 in the Bartlett test was considered significant. Only factors extracted based on the Kaiser criteria (Eigenvalue above 1.2) were considered. These factors were referred to as dietary patterns. To obtain an easy-to-interpret model, the correlation matrix was rotated (orthogonal, varimax). The factor loading over 0.3 was considered significant. If a food group had a loading factor of more than 0.3 in several components, then the food pattern was identified based on the highest value. After rotation, those food groups responsible for the highest load of factors for each factor were identified. Scores that defined each pattern were generated. These scores were the extent to which each individual differed from the average for each score (in standard deviations), therefore higher scores indicated a higher "adherence" to that pattern (17). Dietary patterns were named according to those food groups responsible for the highest load of factors corresponding to each factor. Chi-square test was used for categorical variables and ANOVA for

continuous variables to compare the differences between subjects identified with different food patterns. For non-homogeneous variables t-test was used. Bivariate correlation (Pearson r) was used to identify associations between continuous variables. All data were analyzed using *SPSS Statistics version 20.0, for Windows.*

RESULTS

Subjects general characteristics

We analyzed a group of 118 patients. The general characteristics of the study population are presented in first table.

Daily intake of energy, macronutrients and food groups

Tab. II shows the average intake of energy and macronutrients in the study population, as derived from FETA analysis of the EPIC questionnaire, for the entire study population and with comparison between sexes. We found significant differences between sexes for consumption of total lipids (32.67% in women, *vs.* 30.59% in men, p=0.029) and polyunsaturated fatty acids (PUFA) (6.7% in women *vs.* 5.96% in men, p=0.006). The analysis also generated the daily average intake of the 13 food categories defined by FETA. Although there were some differences in the consumption of food groups between sexes, these were not statistically significant.

TABLE II

Average daily intake of calories, macronutrients and food groups

Energy, macronutrients, food group intake	Total (n=118)	Men (n=55, 46.6%)	Women (n=63, 53.4%)	*p*

SFA, saturated fatty acids; MUFA, monounsaturated fatty acids; PUFA, polyunsaturated fatty acids; SD, standard deviation; *p*, difference between sexes; NS, non-significant

When correlation analyses were conducted between daily intake of food groups and clinical and metabolic parameters, there was a small, but statistically significant inverse correlations between total cholesterol and consumption of nuts and

seeds (r=-.199, *p*=.032). WHR was negatively correlated with consumption of nuts and seeds (r=-.26, *p*=.007) and positively correlated with intake of soups and sauces (r=.262, *p*=0.006). Fasting plasma glucose correlated negatively with meat and derivatives intake (r=-.208, *p*=.024). CRP was positively correlated with the amount of sugar/snacks (r=.189, *p*=.041) and diastolic blood pressure was positively correlated with fish and derivatives intake (r=.198, *p*=.003) (tab. III).

Dietary patterns characterization

There was a high correlation between food groups (KMO = 0.72). Using the principal component analysis, and selecting the varimax rotation, based on the Kaiser criteria and the scree plot (Fig. 1), three food patterns were generated. In the initial solution, these patterns had an Eigenvalue value > 1.2 and accounted for 53.6% of the variance.

The first factor identified that accounted for 29.24% of the variance, was characterized by an increased intake of fat, oil, cereals, potatoes, vegetables, fish, nuts, seeds and fruits. This was named the *Prudent* pattern. The second factor that represented 13.85% of variance and was characterized by increased intake of meat and meat products, eggs and soft drinks, was named the *Western* pattern. Although the sugar/snacks

load did not exceed 0.3, we elected to include it in this pattern since it had the highest loading value, among all three patterns. The third factor that accounted for 10.5% of the variance and was characterized by high intake of milk and derivatives, soups/sauces and vegetables, was named the *Traditional* pattern (tab. IV, fig. 2).

There was a significant difference between patterns, with 21.8% men and 42.9% women included in the *Prudent* pattern, whereas 40% men and 15.9% women belonged to the *Western* pattern (p=0.002). Also, there were significantly more women than men in the *Traditional* compared to the *Western* pattern (p=0.004). Likewise, patients included in the *Prudent* pattern were significantly older than those included in the *Western* pattern (p=0.02). Alcoholic beverages intake was significantly higher in the *Western* compared to the *Prudent* pattern (p=0.005) and patients included in the *Western* pattern had a significantly higher WHR compared to those included in the *Prudent* pattern (p=0.013). HbA1c value was higher in the *Western* pattern (p=0.031) (tab. V).

When correlations analyses between pattern scores and characteristics of the study population were run, there was a significant direct relationship between the *Prudent* pattern and age. WHR was negatively associated with *Prudent* pattern and positively with *Western* pattern (tab. VI).

DISCUSSION

Eating habits are difficult to change even when patients diagnosed with T2DM are motivated to pursue such changes (18). Our study population presents typical characteristics of individuals with T2DM: mature adults (60.85±10.05 years old), with excess body weight (94.9%), hypertension (74.1%) and borderline glycemic control (HbA1c=6.9±1.2). The average duration of the disease in our patients was 5.5 years and they were provided with nutritional therapeutic education, according to current guidelines for the management of diabetes. Indeed, when we assessed the energy and macronutrient intake of our study population, we observed a balance between macronutrients as percentage of total caloric intake, consistent with the recommendations from food guidelines (12). They reported on average daily intake of 48.2% carbohydrates, 31.6% total lipids and 19.2% protein. However average daily energy intake seen in our study was lower than the recommendations for the general population.,explained either by the typical underestimation seen with self-reported methods of investigation (19) or by the fact that patients with excess weight were reducing caloric intake. A close inspection of the data from the analysis of EPIC questionnaire in FETA revealed several nutritional issues in our patients: low intake of fiber (18 g/day), high consumption of SFA

(11% of total caloric intake) and increased dietary cholesterol (336.8 mg/day), although these observations were consistent with FAO reports (20).

Usually, the terms used in the literature to describe dietary patterns are: "healthy or prudent" that are represented by foods or food groups such as fruits, fish, poultry, whole grains and vegetables) (21); "Western", represented by foods or food groups such as red meat, processed meat, sweets, sugar, snacks, high-fat dairy products and French fries) (22), and "traditional" that is represented by foods or food groups that are country specific, such as white rice, beans, beer, processed and fresh meats, for a common Brazilian meal (23), or such as vegetables, seaweeds, soybean products, fish, fruits, miso soup and green tea, for traditional Japanese pattern (24). Out of the three commonly used dietary patterns, *Western* is the one of concern given that its representative food groups have been associated with high prevalence of chronic diseases (25).

The first pattern we identified is the *Prudent* pattern, characterized by an increased intake of fats, oil, cereals, potatoes, vegetables, fish, nuts, seeds, and fruits. The second is the *Western* pattern, characterized by high intake of meat and meat products, eggs and soft drinks. The third is the *Traditional* pattern, characterized by a high intake of milk and derivatives, soups/ sauces and vegetables. A characteristic of our *Western* pattern was high intake of soft drinks. Fructose-sweetened beverages have many adverse effects such as deposition of visceral fat, increased lipid parameters and increased blood pressure and decreased insulin sensitivity in overweight and obese people (26). We found that patients included in the Western pattern had higher WHR and HbA1c values compared to those in the *Prudent* pattern. These improved health outcomes in patients included in the Prudent pattern could be explained by fish consumption, known for its high contents in omega 3 PUFA, nuts consumption which are high in PUFA and MUFA. Despite the high fat and energy content, regular nut consumption was not associated with increased obesity, but instead it offered benefits in weight control (27). These data confirm our results showing a negative correlation between nut intake and WHR. Furthermore, the *Prudent* pattern is characterized by high intake of fruit, vegetables, cereals that may exert hypoglycemic effects and decrease insulin response via increase in fiber, specific vitamins and minerals, flavonoids, carotenoids (28).

Our results did not show significant associations between dietary patterns and blood pressure, which is consistent with other studies (29).

Dietary analyses and metabolic parameters indicate that *Traditional* pattern is much closer to the *Prudent* rather than *Western* pattern in terms of health outcomes. Moreover, soups and sauces that are included in this pattern are part of the traditional Romanian cooking with "borș", a liquid resulting from wheat bran fermentation, and significant amounts of vegetables and greens. Patients included in the Western pattern, were significantly younger than those who adhered to the *Prudent* pattern. It might be that younger individuals are more exposed to the Western influence in their dietary choices or prefer fast foods. This is important and worrisome since adherence to *Western* pattern from an early age may result in increased risk for T2DM. On average, prudent diets were more prevalent in older adults compared to younger adults (30). In

general, food pattern studies have found that older people, and women in particular, consume less red meat, whole milk and other fatty foods and consume more fruits and vegetables than younger people (31). Higher standard of living, higher education, nutritional knowledge has been associated with a healthy/"prudent" dietary pattern (32). It has been shown that people with lower education have more financial restraints and limited access to healthy food (33). In our study, individuals with higher education degrees and those currently retired, have adhered to the Prudent pattern, whereas those with lower education and employed tended to adopt the Western pattern.

The Romanian Dietary Guidelines promotes a healthy nutrition based on consumption of cereals, fruits, vegetables, foods with low fat content and reduction of processed and high sugar foods (34). Dietary patterns recently studied in the general Romanian population showed a Prudent pattern characterized by large intake of fish, vegetables, legumes, fruits and soymilk, adopted by elderly women and those with a higher education level (35).

Although we have included a large number of T2DM patients, our study has several limitations such as the observational design and lack of a control group consisting of individuals without diabetes. Also, since most subjects were from the urban areas, we cannot make a clear distinction between urban and rural dietary patterns. These patterns are from the Iasi County, situated in the north-eastern region of the country thus data from other regions of the country will be useful in order to get a broader picture of dietary patterns in this population.In addition, our study cannot identify the effects of different oral hypoglycemic treatments or other pathologies that may have influenced patients' food selections.

Also, our subjects did not complete a physical activity questionnaire, thus the extent to which physical exercise might have influenced food selection is difficult to ascertain. Notwithstanding these limitations, our findings demonstrate the value of dietary patterns in nutritional therapy in T2DM in Romanian population.

CONCLUSIONS

This is the first clinical observational study to identify dietary patterns in Romanian patients with type 2 diabetes. Using principal component analysis on 13 food groups derived from the EPIC questionnaire has allowed us to identify three food patterns: *Prudent*, *Western* and *Traditional*. The *Western* pattern was associated with detrimental consequences on abdominal adiposity and glycemic control compared to the *Prudent* pattern. The *Traditional* pattern seems closer to the *Prudent*, than the *Western* pattern. Studies on food patterns, food selections and dietary preferences in patients with metabolic disorders including diabetes in Romania are scarce. Given the differences in country specific food patterns and their impact in disease management, identifying food patterns in patients with Type 2 Diabetes Mellitus could help tailor educational programs in order to target diet and overall lifestyle optimization meant to slow down disease progression and its complications.

THE EFFECTS OF CARDIAC REHABILITATION ON RESTING HEART RATE AND BLOOD PRESSURE IN HEART FAILURE PATIENTS (Abstract): Our study analyzed the efficiency of cardiac rehabilitation programs (CRP) in decreasing resting blood pressure (RBP) and heart rate (RHR), two important prognosis tools for heart failure (HF) patients. **Materials and methods:** A retrospective cohort study was conducted in a regional hospital over a 3-year period. A total of 137 HF patients, who benefited from a physical based CRP with a mean duration of 10 days, were divided into 2 groups according to the severity of their symptoms. All the patients underwent physical and paraclinical evaluation, including cardiopulmonary testing before starting the rehabilitation. RHR and RBP were measured before and at the end of the program. **Results:** Most of the patients in this study were men (73.7%) and hypertensive (55.5%), while the mean age of study's participants was 65.24 ± 9.76 years. A significant decrease was observed in the RHR after rehabilitation (81.37 ± 8.65 bpm *vs*. 77.79 ± 6.77 bpm, p = 0.004). Significant improvements were also observed in resting systolic blood pressure (BP), the mean values decreasing with more than 4% after rehabilitation (122.06 ± 16.2 mmHg *vs*. 116.91 ± 12.14 mmHg, p = 0.001). Mean diastolic BP also decreased at the end of the program (73.81 ± 12.05 mmHg *vs*. 72.8 ± 10.36 mmHg, p = 0.28). Though non-significant, age and baseline HR and BP appeared to be important therapy response predictors. Younger patients and those who had higher HR and BP at the beginning of the program benefited most from CRP. **Conclusions:** A short term CRP proved to be efficient in reducing RHR and RBP of HF patients, while age, baseline HR and baseline BP may be potential therapy response predictors. **Keywords:** HEART FAILURE, CARDIAC REHABILITATION, RESTING HEART RATE, RESTING BLOODPRESSURE.

Heart failure (HF) is the predicted outcome of most cardiovascular diseases (CVD), with an incidence and prevalence which are getting closer to epidemical proportions (1, 2). Consequently, the economic pressure generated by HF upon systems

worldwide is constantly rising, the associated treatment costs being estimated to increase up to 108 billion dollars per year (3, 4).

Effort capacity diminution is one of the main health problems for people suffering from HF. It is also a cause of quality-of-life (QoL) impairment and an important risk factor and prognosis tool for hospitalization and mortality (5, 6). The physiopathology behind this is complex, systolic and diastolic dysfunction having central roles. To maintain the cardiac output, despite a reduced stroke volume, the cardiovascular system activates certain compensatory mechanisms during rest, so that they become insufficient during effort. One of these mechanisms is tachycardia, effort capacity decreasing proportionally with the resting heart rate (RHR). Therefore, its control is an important target when treating these patients, helping increase their quality of life (QoL) and reduce their mortality. Furthermore, blood pressure (BP), is an independent predictor of effort capacity for HF patients and an important risk factor for cardiovascular events, as well, its control being equally important (7, 8).

Apart from pharmacological therapies, which proved their efficiency on reducing the mortality and morbidity rates of HF patients, cardiovascular rehabilitation programs (CRP) are a treatment option increasingly frequently used. Their efficiency is widely recognized especially for patients with moderate-severe symptoms (NYHA II and III), regardless the ejection fraction subtype, the latest guidelines recommending them for all the patients (7, 9). Considering its proved ability to reduce sympathetic stimulation, to down-regulate the funny channels, HCN4 and its effects on neuroendocrinological and vascular level, physical training may produce an important decrease in BP and RHR and consequently an increase of effort capacity and QoL (7, 10).

Our study aimed to assess the clinical and paraclinical profile of HF patients, who underwent a CRP at a regional hospital and to determine its efficiency in reducing resting BP and HR.

MATERIAL AND METHODS

We performed a retrospective cohort study, which included patients diagnosed with NYHA I-III heart failure, who underwent a CRP with a mean duration of 10 days, at a local hospital in Iasi, during a 3-year period. HF diagnosis was defined according to the European Guidelines for Heart Failure, using clinical, echocardiographic and paraclinical (NT-proBNP) criteria. The exercise program was adapted to each patient, using the cardiopulmonary testing and consisted of daily aerobic exercises.

Our cohort included 137 patients with HF, who were divided into two groups according to the severity of their symptoms: group A included patients with NYHA I and II heart failure and group B with more severe symptoms (NYHA III). We excluded from the study those patients for whom we did not have access to all the information needed, especially the resting BP (RBP) and HR before and after the rehabilitation and those patients with NYHA IV HF, who were not able to undergo an exercise-based CRP. All the information was collected anonymously using the hospital's and the rehabilitation department's database. The study protocol received the approval of the ethics committee and the hospital board.

All the patients included into the study underwent complete clinical examination and basic paraclinical testing, consisting of medical history and clinical evaluation, echo-cardiography study, biochemical testing, hemodynamical assessment at the be-

ginning and at the end of the rehabilitation period. Laboratory testing included kidney and hepatic function, fasting glycemia, complete blood count and lipidic profile.

Statistical analysis

The statistical analysis was performed using *SPSS 11.0 software.* For the continuous variables, we calculated the maximum, minimum and the mean values and we also determined the standard deviation. The categorial values are represented as absolute values and percentage. The statistical significance was defined by a $p < 0.05$ and was evaluated using the *t-student test* and the *chi square test.*

RESULTS

The main characteristics of our study group are presented in table I. Most of the included patients were men (73.7%) and hypertensive (55.5%). Apart from hypertension, dyslipidemia was the most common cardiovascular risk factor among these patients (38.7%), followed by diabetes (34.4%) and obesity (23.35%). We did not observe any statistical correlation between the severity of HF and the presence of anemia ($p = 0.507$), patients' gender ($p = 0.194$) or cardiovascular surgical history. Concerning the effects of CRP on the RHR and BP, significative impact was observed in both groups.

TABLE I.
Clinical and paraclinical characteristics of the two-study group

Parameter	Total patients – 137	Group A – 81 (59%) patients	Group B – 56 (41%) patients	p
Mean age (y. o.)	65.24 ± 9.76	64.04 ± 9.48	66.96 ± 9.99	0.04
Gender report				
○ Men	101 (73.7%)	63 (77.7%)	38 (67.85%)	0.19
○ Women	36 (26.3%)	18 (22.3%)	18 (32.15%)	
Surgical history				
○ Revascularization	58 (42.33%)	36 (44.4%)	22 (39.28%)	
○ Valvuloplasty	54 (39.41%)	31 (38.27%)	23 (41.07%)	0.07
○ Both	14 (10.21%)	8 (9.87%)	6 (10.71%)	
○ None	11 (8.05%)	6 (7.4%)	5 (8.92%)	
GFR (mL/min/1.73m^2)	66.83 ± 16.55	68.86 ± 13.73	63.87 ± 19.72	0.06
Anemia				
○ Hb<12mg/dL (women)	91 (66.42%)	52 (64%)	39 (69.6%)	0.53
○ Hb<13mg/dL (men)				
Lipid profile				
○ Total cholesterol (mg/dL)	158.59 ± 43.44	159.02 ± 46.04	157.96 ± 39.67	0.43
○ LDL-C (mg/dl)	87.45 ± 33.77	87.65 ± 36.06	87.15 ± 30.48	0.45
○ HDL-C (mg/dl)	44.35 ± 15.004	43.14 ± 16.69	46.11 ± 12.07	0.17
○ Triglycerides (mg/dl)	133.91 ± 65.5	141.15 ± 69.01	123.46 ± 59.11	0.05
Diabetes	47 (34.3%)	30 (37.03%)	17 (30.35%)	0.41
Mean RHR (bmp)	81.37 ± 8.65	82.04 ± 9.37	80.41 ± 7.46	0.07
Mean resting BP (mmHg)				
○ Systolic	122.06 ± 16.2	123.71 ± 17.36	119.67 ± 14.17	0.06
○ Diastolic	74.27 ± 11.29	73.81 ± 12.05	74.92 ± 10.17	0.28

BP = blood pressure, bpm = beats per minute, GFR = glomerular filtration rate, Hb = hemoglobin, HDL-C = high density lipoprotein cholesterol, LDL-C = low density lipoprotein cholesterol, RHR =resting heart rate, y. o. = years old

Resting heart rate

At the end of the CRP, 93 (67.8%) of the patients presented lower HR values during rest, the mean values decreasing by 4.4% (3.58/min) for entire group, compared to the beginning of the study ($p < 0.05$). In group A, we observed better results, 60 patients (74.07%) presenting lower RHR at the end of the program, compared to 33 (58.92%) in group B ($p = 0.061$). Furthermore, we observed a higher difference between the mean values of RHR before and after the rehabilitation, in the first group (5.56%, $p < 0.05$ *vs.* 2.68%, $p < 0.05$), the difference being statistically significant ($p < 0.05$) (tab. II).

TABLE II.

RHR response to rehabilitation

	Total	Group A	Group B
Baseline (bmp)	81.37 ± 8.65	82.04 ± 9.37	80.41 ± 7.46
After rehabilitation (bpm)	77.79 ± 6.77	77.48 ± 7.05	78.25 ± 6.37
Difference (bpm)	3.58 (4.4%)	4.56 (5.56%)	2.16 (2.68%)
P value	**0.00463**	**0.00302**	**0.00511**

Bpm=beats per minute

Systolic blood pressure (SBP)

At the end of the study, SBP varied among the included patients between 92 and 156 mmHg, the mean value decreasing from 122.06 ± 16.2 mmHg to 116.91 ± 12.14 mmHg, the 5.15 mmHg (4.22%) the difference being statistically significant ($p = 0.001$). The statistical analysis for each group, revealed a decrease of the mean values from 123.71 ± 17.36 mmHg to 117.28 ± 11.93 mmHg, for group A, respectively from 119.67 ± 14.17 mmHg to 116.37 ± 12.53 mmHg for group B, the differences of 6.43 mmHg (5.19%), respectively 3.3 mmHg (2.76%), being statistically significant ($p = 0.003$, respectively $p = 0.009$) (tab. III). Moreover, a decrease in resting SBP was observed among 92 patients (62.5%), 52 from group A and 35 from group B, which represented 70.37%, respectively 62.5% from each group, the difference not having statistical significance ($p = 0.334$).

TABLE III.

SBP response to rehabilitation

	Total	Group A	Group B
Baseline (mmHg)	122.06 ± 16.2	123.71 ± 17.36	119.67 ± 14.17
After rehabilitation (mmHg)	116.91 ± 12.14	117.28 ± 11.93	116.37 ± 12.53
Difference (mmHg)	5.15 (4.22%)	6.43 (5.19%)	3.3 (2.76%)
P value	**0.00158**	**0.00339**	**0.0097**

Diastolic blood pressure (DBP)

The CRP was not as efficient on the DBP as it was on the systolic one. The statistical analysis revealed a decrease of the mean values of DBP for the entire study group of only 0.7 mmHg which was not significant ($p = 0.28$). Analyzing the data for each group, we obtained the same

results. The mean values decreased with 1.01 mmHg in group A, respectively with 0.26 mmHg in group B (p = 0.28, respectively p = 0.88) (tab. IV). Furthermore, lower DBP values were observed among 69 patients (50.36%), 42 (51.85%) from group A and 27 (48.21%) from group B (p = 0.625).

TABLE IV.
DBP response to rehabilitation

	Total	Group A	Group B
Baseline (mmHg)	73.81 ± 12.05	74.92 ± 10.17	74.27 ± 11.29
After rehabilitation (mmHg)	72.8 ± 10.36	74.66 ± 8.7	73.56 ± 9.73
Difference (mmHg)	1.01 (1.36%)	0.26 (0.34%)	0.7 (0.94%)
P value	0.28	0.88	0.28

DISCUSSION

CVD remain the first cause of mortality worldwide, HF being the main outcome, with its incidence and prevalence increasing, especially in low or middle-income regions (11, 12). The efficiency of CRP in improving the QoL, reducing the morality and the hospitalization rate of HF patients, has already been tested and confirmed by numerous studies so that this type of treatment represents a class IA indication in the current guidelines (9, 13). Even if numerous studies have already validated the efficiency of physical activity in reducing RHR and RBP, very few tested the effects of a CRP of such a short duration.

On epidemiological level, in our study, both the mean age and the gender report of the patients diagnosed with HF matched the date already existed in literature. Consequently, we can reaffirm that HF is a pathology mainly affecting elderly patients and men. This affirmation is valid in most parts of the world, except the low-income regions, such as Sub-Saharan Africa, where HF has a predominantly infectious etiology (14, 15).

67.8% of the patients included in the study presented a decrease in the RHR. The CRP was more efficient for those with less severe symptoms, among whom we observed a better response, with lower RHR at the end, compared to the baseline values (4.56/min *vs.* 2.16/min). Considering the baseline RHR values and the mean age in each group, our results match those obtained in a meta-analysis, which included 181 studies that evaluated the effects of physical training on RHR. The study concluded that the effects of physical training on HR are proportional to the initial values of HR and inversely proportional to the age, without finding a correlation between these two variables. Consequently, we can affirm that CRP may be more efficient, at least when it comes to decreasing RHR, among younger patients (16).

Significant decrease of resting SBP, but not of DBP was observed for all the patients in our study. Similar to RHR, those patients who presented higher baseline SBP values responded significantly better. Our results align to those observed in a meta-analysis which evaluated the impact of physical training on the BP and included 44 randomized controlled studies with physical training programs lasting from 4 to 52 weeks. The meta-analysis concluded that

the baseline BP influenced the BP response and hypertensive patients had a better response than normotensives, with a higher decrease in resting BP values (-2.6/-1.8 mmHg *vs.* -7.4/-5.8 mmHg) (17). A smaller meta-analysis conducted over 23 studies observed the same relationship between physical training induced BP reduction and the baseline BP. The particularity of this study was that BP was evaluated using ambulatory blood pressure monitoring (ABPM), giving a more detailed result (18).

An explanation to our findings could be Wilder's law of initial value, stating that „the higher the baseline level of a physiologic function is, the grater is the response to function-depressing agents". After being published, Wilder's law has been investigated and reconfirmed by numerous researchers worldwide and from all branches of medicine, especially cardiology and despite being published in 1931 it still addresses nowadays problems (19, 20).

The most important limitations of our study are represented by the small sample size and the absence of a control group, which would have let us evaluate more accurately the impact of CRP on HF patients. In addition to this, the lack of ejection fraction-based classification of HF made it impossible to evaluate whether the left ventricle systolic dysfunction influences the response to rehabilitation or not, thus further studies are required to address these limitations.

CONCLUSIONS

Our study reconfirmed that CRP, even on a shorter period, remain an important treatment tool for HF patients, especially for controlling the resting HR and BP. These baseline parameters and the age of the patients represent important therapy response predictors.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest, and they did not receive any specific funding regarding the scientific research.

NEWS

AVACOPAN – A NEW TREATMENT FOR ANCA-ASSOCIATED VASCULITIS

Antineutrophil cytoplasmic antibody (ANCA)-associated vasculitis can lead to decrease in kidney function, organ damage and side effects related to the medication used for treatment, such as glucocorticoids. The C5a receptor inhibitor avacopan is being studied in a randomized, controlled study for the treatment of ANCA-antibody associated vasculitis. Patients were divided in two groups which received either avacopan or prednisone on a tapering schedule. Both groups received rituximab or cyclophosphamide followed by azathioprine. Avacopan was superior to prednisone in sustaining remission at the end of the trial (David R.W. Jayne, M.D., Peter A. Merkel, M.D., M.P.H., Thomas J. Schall, Ph.D., and Pirow Bekker, M.D, Ph.D. for the ADVOCATE Study Group. Avacopan for the Treatment of ANCA-Associated Vasculitis. *N Engl J Med* 2021; 384:599-609 / doi: 10.1056/NEJMoa2023386).

INTERDISCIPLINARY IN MANAGING HIV/AIDS INFECTED PATIENTS – THE IMPORTANCE OF TEAMWORK

INTERDISCIPLINARY IN MANAGING HIV/AIDS INFECTED PATIENTS - THE IMPORTANCE OF TEAMWORK (Abstract): The role of an interdisciplinary approach is useful in maintaining a good quality of life and low mortality rates among HIV-infected people. A better understanding of the evolution of comorbidities may help to improve the clinical management of HIV/AIDS patients. **Material and methods:** We performed a retrospective study between 1st of January and the 1st of December 2022 including 1157 patients who have been admitted to Iasi HIV/AIDS Regional Center, from "Sf. Parascheva" Clinical Hospital of Infectious Diseases, in order to identify the main factors that lead to major imbalances in the status of patients with HIV/AIDS infection, highlighting the most common comorbidities. **Results:** In the study period, 1,157 (70.46%) patients were admitted, and 89 cases (5.48%) were newly diagnosed. The study patients were virologically and immunologically evaluated. It was observed that 12.62% of cases had a CD4 level between 1-200 cells/mm^3, in 58.95% of cases the CD4 value was between 201-500 cells/mm^3, and 28.44% of patients had CD4 over 501 cells/mm^3, with an average CD4 level of 375.28 cells/mm^3. The average of HIV viral load was 107.46 copies/mL. Out of the total of 1157 cases, 146 (12.62%) patients had a CD4 level under 200 cells/mm^3, considered to have a viro-immunological failure, and they were recommended other antiretroviral regimens, most of them being prescribed a single tablet regimen. Depending on the related comorbidities, 62.32% of the 1157 cases admitted in our clinic required interdisciplinary examinations. In descending order, the following conditions were the most common comorbidities that the patients presented: metabolic (45.20%), dermatological (31.20%), ENT (12.79%), gastrointestinal (10.29%), infectious diseases (9.16%), cardiovascular issues (5.10%), psychiatric disorders (4.06%), pulmonary (3.54%), neurological (2.68%), ophthalmic (1.21%), and hematological conditions (0.78%). Out of the newly diagnosed cases, 85.39% were recommended single tablet regimen and in 14,61% cases were given a regimen that took into account their comorbidities. A large percentage of patients (82.20%) were evaluated through psychological consultation to ensure compliance and adherence to antiretroviral treatment, thus helping a better understanding of their disease for effective management. **Conclusions:** Multidisciplinary strategies for HIV have become more prevalent as various scientific environments have evolved. Assessing risk behaviors, clinical manifestations, health status, psycho-behavioral and cultural factors, as well as HIV assistance have emerged. **Keywords**: HIV/AIDS, COMORBIDITIES, ANTIRETROVIRAL THERAPY, INTERDISCIPLINARY.

Over the past four decades, researchers highlighted many challenges in addressing the pandemic with human immunodeficiency virus (HIV). The challenges include geographical, cultural and economic characteristics of affected regions, which could exert influences on how the epidemic presents itself, including its prevalence, severity, accessibility, treatment adherence and associated factors. Stigma, discrimination and barriers to treatment due to poverty are social impacts that can hinder treatment effectiveness and prevention efforts. Furthermore, we must adopt a multi-disciplinary approach to address this disease. HIV and AIDS (acquired immunodeficiency syndrome) are and remains complex diseases that requires extensive, coordinated care including clinical, psychological and social factors to ensure positive outcomes in HIV/AIDS infected patients (1, 2). Specialists have an important contribution to the health care system, specifically in increasing patient awareness by importance of medication adherence, encouraging behavioral changes and providing additional access to care for patients with HIV infection (3). Despite the remarkable progress in medical management, HIV infection continue to be an extremely stigmatized and socially intricate disease. Therefore, it is important to provide psychological support to newly diagnosed patients, by an experienced HIV counselor, as they adjust to HIV diagnosis and get ready to start antiretroviral therapy (4).

People with HIV who are effectively treated with antiretroviral treatment (ART) and with effective sustained viral suppression have a near-normal life expectancy. Even in the era of ART, the identification, mitigation and treatment of HIV-associated comorbidities continue to be a challenge that must be addressed (5).

Obesity, diabetes mellitus, cardiovascular disease, liver disease and neurocognitive illness comorbidities, all contribute significantly to the morbidity and mortality of people with HIV (6).

Dysbiosis, which includes a decline in butyrate-producing bacteria in the general population, is linked to the development of diabetes. A reduced relative abundance of butyrate-producing bacteria and its link with signs of microbial translocation and immunological activation have been observed in people with HIV, despite the lack of a correlation with diabetes (6).

Roomaney *et al*. found that the most common comorbidity among HIV-positive individuals was estimated to be hypertension. Also, tuberculosis (infection with *Mycobacterium tuberculosis)*, TB was the next most prevalent disease, followed by diabetes, heart disease and cancer (7).

Results revealed patterns that show stable hospitalization rates for people with HIV overall, with a drop in AIDS-defining illnesses and an increase in other comorbidities disorders (respiratory, cardiovascular and gastrointestinal causes), (8, 9).

The role of a multidisciplinary approach is useful in maintaining a good quality of life and low mortality rates among HIV-infected persons. A better understanding the evolution of comorbidities may help to improve the clinical management of HIV/AIDS patients including screening for risk factors and optimal selection of ART to balance HIV outcomes. Providing optimal care and treatment to people living with HIV/AIDS is an ongoing challenge (8, 9).

MATERIAL AND METHODS

We performed a retrospective study between January and December 2022 includ-

ing 1157 patients who have been admitted to Iasi HIV/AIDS Regional Center from "St. Parascheva" Clinical Hospital of Infectious Diseases, in order to assess the importance of a multidisciplinary approach in managing patients diagnosed with HIV/AIDS.

RESULTS

Iasi HIV/AIDS Regional Center cares for a total of 1642 patients from 6 counties - Bacău, Botoșani, Iași, Neamt, Suceava, and Vaslui. The patients benefit of periodic clinical, biological, and viral-immunological evaluations from a multidisciplinary team of infectious disease doctors, gastroenterologists, ophthalmologist, ENT doctor, dermatologist, radiologists, psychologist, nurses, and social workers.

Between the 1st of January and the 1st of December 2022, 1,157 (70.46%) patients were admitted, and 89 cases (5.48%) were newly diagnosed. They were all evaluated in our clinic.

Regarding the patients distribution by county, it was observed the following: Iași, 22.73% of patients; Bacău, 18.67%, Botoșani 15.99%, Neamt, 19.53%, Suceava, 16.68%, Vaslui, 6.4% from patients (fig. 1).

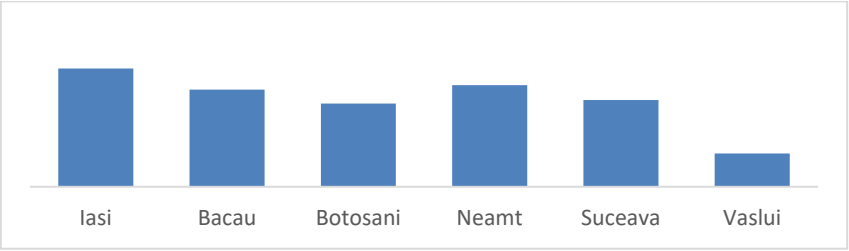

Fig. 1. Distribution of HIV/AIDS cases by county

From total number of hospitalized patients, predominantly 664 (57.39%) were male and 493 (42.61%) were female (fig. 2). The majority of the cases were young adults with ages between 21- 40 years old - 774 (66.9%) patients, followed by the age group 41-60 - 304 (26.27%) patients, 61-80 - 48 (4.15%) patients, and 0-20 - 31 (2.68%) patients (fig. 3). The average age of the study group is 37.78 years old, demonstrating the impairment of young adults.

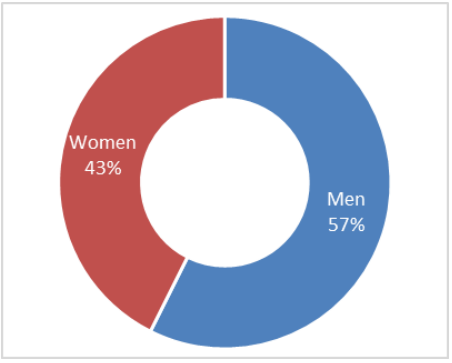

Fig. 2. Distribution of studied cases by gender

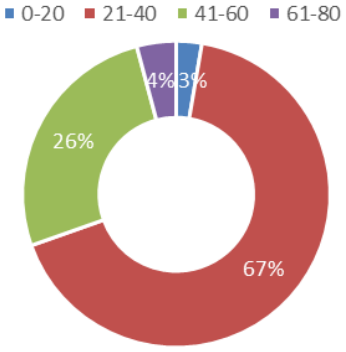

Fig. 3. Distribution of studied cases by age

Regarding the hospitalization way, 577 patients (49.87%) were admitted as outpatients and 580 patients (50.13%) were hospitalized, with an average of 5.72 days of hospital care. The patients were periodically evaluated. Taking into consideration the number of hospitalizations, 690 (59.64%) were admitted just once, 151 (13.05%) between 2 and 4 times, 54 (4.67%) between 5-7 times, 109 (9.42%) between 8-10 times and 153 (13,22%) over 11 times (fig. 4). It was observed that more than half of the study group required only one hospitalization while patients with more than one were most often associated with comorbidities that demanded multidisciplinary evaluations.

All of the patients from the Iasi HIV/AIDS Regional Center were virologically and immunologically evaluated. It was observed that 12.62% of cases had a CD4 level between 1-200 cells/mm^3, in 58.95% of cases the CD4 value was between 201-500 cells/mm^3, and in 28.44% of patients had CD4 over 501 cells/mm^3, with an average CD4 level of 375.28 cells/mm^3 (fig. 5). The average of HIV viral load was 107.46 copies/mL.

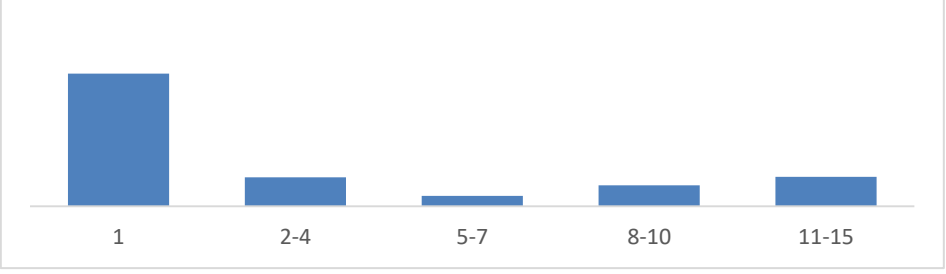

Fig. 4. Distribution of studied cases by number of hospitalizations

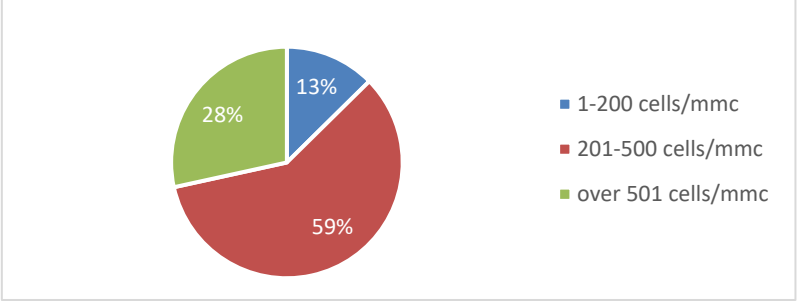

Fig. 5. Distribution of study cases by CD4 levels

Out of the total of 1157 cases, 146 (12.62%) patients had a CD4 level of under 200 cells/mm^3, were considered to have a viro-immunological failure, and they were recommended other antiretroviral regimens, most of them being prescribed a single tablet regimen.

Throughout the studied period, 164 (14.17%) patients needed an antiretroviral treatment (ART) switch. The most common reason was regimen simplification (66%), followed by viro-immunological failure (19%) and comorbidities (11%), (fig. 6).

Between January and December 2022, in Iași HIV/AIDS Regional Center, there were 89 newly diagnosed patients. They

benefited from clinical and biological investigations, and interdisciplinary consultations in order to better understand the infection they are dealing with, and to start antiretroviral treatment tailored to their needs. Out of the newly diagnosed cases, 85.39% were recommended a single tablet regimen and in 14.61% cases, was chosen a regimen that took into account their comorbidities.

	%	0.69	0.52	1.21
Hematological diseases	n	4	5	9
	%	0.35	0.43	0.78
Pulmonary diseases	n	28	13	41
	%	2.42	1.12	3.54

From a total of 1,157 cases hospitalized in our clinic in the mentioned study period, 62.32% required multidisciplinary evaluations, depending on the associated comorbidities. The most common comorbidities presented in the study group were metabolic, dermatological, ENT (otorhinolaryngological), gastrointestinal, infectious diseases, cardiovascular ailments, psychiatric disorders, pulmonary, neurological, ophthalmic and hematological (fig.7, tab. I).

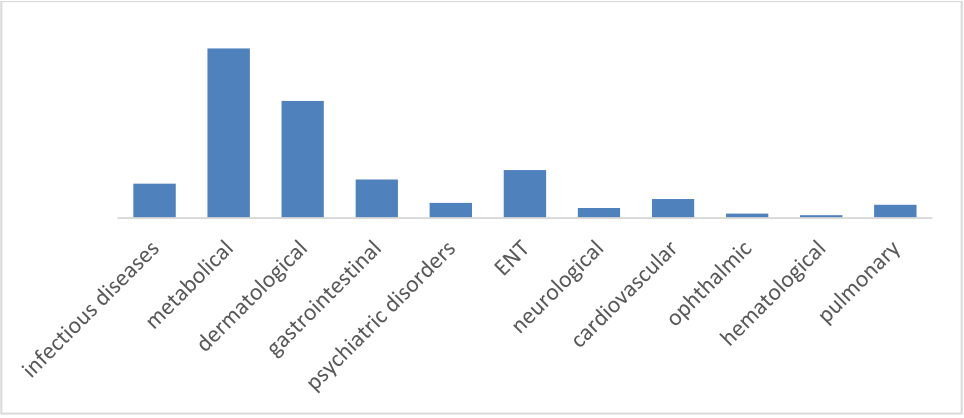

Fig. 7. Distribution of study cases by comorbidities

The metabolically disorders consisted in signs of lipodystrophy, central adiposity, dyslipidemia, increased risk of cardiovascular disease and atherosclerosis. This was observed to be caused by HIV infection and some antiretrovirals. The patients with lipid dysfunction were recommended changes in diet and lifestyle, and assessment in the internal medicine clinic, and in some cases, they benefited from ART switch.

Dermatological disorders were oral candidiasis, herpetic lesions, syphilis, anogenital condylomas, and Kaposi's sarcoma.

The most frequent ENT diseases were represented by sinusitis and otitis, which were evaluated in our clinic.

Gastrointestinal diseases were evaluated biologically, by ultrasound and computer tomograph, the patients received hygienic-dietary recommendations and specific treatment.

Opportunistic infections of HIV/AIDS were evaluated at each periodic visit of the patients in our clinic.

The neurological, cardiovascular, pulmonary, hematological, and psychiatric conditions were assessed, and later the patients received recommendations for consultation in specialized clinics depending on the disease.

Ophthalmic disorders

Were found in 14 cases, 2 patients had *Molluscum contagiosum* on eyelids, 3 cases with *Candida* keratitis, 2 patients had *Cytomegalovirus* retinitis, in 2 cases, *Herpes* keratitis, and in 5 cases was established the HIV-retinopathy diagnosis (fig. 8).

Out of the total of 14 patients with ophthalmic disorders, 3 (21.43%) cases had CD4 levels over 200 cells/mm^3, and 11 (78.57%) cases, under 200 cells/mm^3, with an average of 132.71 cells/mm^3. The average of HIV viral load was 1.025.000 copies/mL (fig. 9).

They were recommended ART switch to a single tablet regimen and specialized

ophthalmological treatment. In 5 cases were associated other conditions, such as oral candidiasis, liver disease and *Cytomegalovirus* infection.

At the one-month evaluation, 9 patients had CD4 level over 200 cells/mm^3 and 5 patients had a CD4 level under 200 cells/mm^3.

Fig. 8. Distribution of ophthalmic diseases in the HIV/AIDS study group

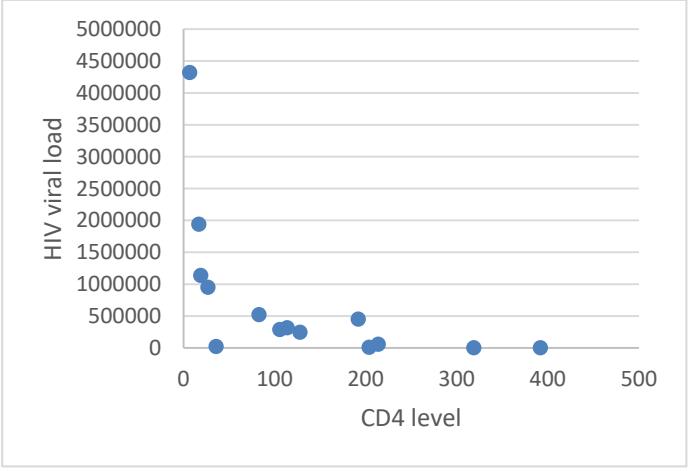

Fig. 9. Distribution of HIV cases associating ophthalmic diseases by CD4 and HIV viral load

A large percentage of patients (82.20%) were evaluated through psychological consultation to ensure compliance and adherence to antiretroviral treatment, thus helping a better understanding of their disease for effective management.

DISCUSSION

The several elements of the HIV multidisciplinary team on ART adherence are examined in this study. Increased attention has been paid to the needs of people with HIV, the chronic diseases treatment. To address the varied demands of people with HIV, interdisciplinary care has evolved as well.

Depending on the related comorbidities, 62.32% of the 1157 cases admitted in our clinic required interdisciplinary examinations. In descending order, the following comorbidities were found metabolic (45.20%), dermatological (31.20%), ENT (12.79%), gastrointestinal (10.29%), and infectious diseases (9.16%), cardiovascular

(5.10%), psychiatric disorders (4.06%), pulmonary (3.54%), neurological (2.68%), ophthalmic (1.21%), and hematological conditions (0.78%).

Roomaney *et al*. found that cardiovascular diseases were more frequent in people with HIV (especially hypertension: 13.3%), next prevalent comorbidities were pulmonary diseases (Tuberculosis was the main cause: 3.5%), followed by metabolic diseases, such as diabetes (3.0%) and cancer (0.4%). Elderly people were more likely to get any of the diseases. The prevalence of diseases like cancer, diabetes, heart disease, and hypertension were higher in women (7).

Katano *et al*. showed that in a cohort of a total of 225 cases opportunistic infectious disease were most frequent (94.4% cases of *Cytomegalovirus* infection and *pneumocystis* pneumonia). The prevalence of non-Hodgkin lymphoma and Kaposi's sarcoma was 37.9% and 15.2%, respectively for people with HIV who had received ART from 1985 to 2012 (10).

Pourcher *et al*. found that people with HIV had significantly higher rates of alcohol misuse (5.8%), chronic renal disease (1.2%), cardiovascular disease (7.4%), dyslipidemia (22%), and hepatitis B (3.8%). Other comorbidities such anemia, malnutrition, mental conditions, and tumors were also more common (11).

Funke *et al*. observed that the most common comorbidities were vitamin D deficiency (29.1%), depressive episodes (27.8%), arterial hypertension (16.3%), and hypercholesterolemia (10.8%) in patients with HIV in Germany (12).

Our results may vary compared to other studies. It is important that physicians should provide patients with varied needs extra care and attention if they want to develop the most effective healthcare plans available.

The global trend in HIV research has been increasing in both quantity and interdisciplinary approaches (13).

CONCLUSIONS

Multidisciplinary strategies for HIV have become more prevalent as various scientific environments have evolved. Assessing risk behaviors, clinical manifestations, health status, psycho-behavioral and cultural factors, as well as HIV assistance have emerged. To provide culturally significant and contextualized evidence of effective therapies to efficiently prevent and manage the condition, more research is needed.

The multidisciplinary approach in the HIV/AIDS research is not surprising. It is absolutely necessary for the scientific fields to intertwine in order to consolidate interdisciplinary.

It is important to identify the main factors that lead to major imbalances in the status of patients with HIV/AIDS infection, whether we are talking about factors related to the disease, community, social factors or factors related to adherence to antiretroviral therapy.

The interdisciplinary approach in HIV/AIDS infection is essential to reach these targets.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest, and they received no funding regarding this scientific research.

ETHICAL APPROVAL

The current study was approved by the Ethics Committee of "Sf. Parascheva" Clinical Hospital of Infectious Diseases, Iasi, Romania.

THE HISTOPATHOLOGICAL AND IMMUNOHISTOCHEMICAL PROFILE OF MALIGNANT BREAST TUMORS IN NORTH-EAST ROMANIA (Abstract): Studies using gene expression profiling have identified five major subtypes of breast cancer, apart from the traditional hormone receptor positive or negative ones: luminal A, luminal B, the HER2 group, the basaloid carcinoma group and the "normal breast-like" group. **Material and methods:** In this retrospective study, 281 patients admitted to the Regional Institute of Oncology Iasi and the Clinical Hospital of Obstetrics and Gynecology Cuza Voda Iasi were included, for whom the oncological records, the operative protocols of the operating room, the unique register of the service were studied; the pathological anatomy and observation sheets were considered for a period of 8 years: 2015-2022. For all 281 invasive mammary carcinomas diagnosed on hematoxylin-eosin staining, they were classified into one of the corresponding histopathological types and subtypes according to WHO criteria. **Results:** The histopathological study allowed: 1. invasive ductal carcinoma NOS (not otherwise specified - non-specific type of invasive ductal carcinoma)-193 cases (68.68%),2. invasive lobular carcinoma-42 cases (14.94%). Immuno-labeling analysis Estrogen receptors (ER) were positive (Allred score ≥ 3) in 61% of cases (169 patients), and progesterone receptors (PR) in 64% of cases (180 patients). Ki 67 immunolabeling analysis highlighted: the presence of positivity in all cases studied, overexpression of the p53 protein in 99 cases and HER 2 immunoassays allowed the highlighting of 42 cases. Identifying cases with p53 protein mutations can select a group of patients with a higher risk of recurrence and death, and testing p53 expression in HER2 positive patients identifies the subgroup with more aggressive tumors that will benefit from a more aggressive treatment. **Conclusions:** The most common histological types were *invasive ductal* carcinoma in 90% of patients. TNM stages was as follows: stage I in 9 cases (3.2%), stage II in 88 cases (31.49%), stage III in 138 cases (48.93%), stage IV in 31 cases (11.03%) ER+/PR- phenotype were more frequent over 50years and tumors larger than 2 cm. Patients under 50 years presented twice as often HER2 positive tumors. Ki67 immunostaining seems to be associated with an unfavorable prognosis (2% of cases in the present study). p53 overexpression occurs most frequently in patients under 50 years, with tumors larger than 2 cm. **Keywords**: BREAST CANCER, DUCTAL CARCINOMA, LOBULAR CARCINOMA, ER, PR, KI67, P53, HER2.

Recently, a variety of molecular techniques, especially the expression profile of certain genes, have redefined the classification of breast cancer from the point of view of prognosis, evolution and expected response to treatment (1).

Studies using gene expression profiling have identified five major subtypes of breast cancer, apart from the traditional hormone receptor positive or negative ones: luminal A, luminal B, the HER2 group, the basaloid carcinoma group and the "normal breast-like" group (2, 3) (tab. I)

Three immunohistochemical markers are used in clinical practice for the molecular classification of breast cancer: estrogen receptors (RE), progesterone receptors (RP) and HER2 expression (4). The best differentiated breast tumors are RE+, RP+ and HER2-, while poorly differentiated tumors are RE-, RP- and HER2+. Exceptions are medullary carcinomas (triple negative), basaloid carcinomas (triple negative) and micropapillary carcinoma (triple positive) (5, 6, 7). Luminal A category carcinomas have a better prognosis, while the basaloid subtype is the most aggressive type of cancer.

TABLE I

The immunophenotype of breast carcinoma

MOLECULAR SUBTYPE	IMMUNOHISTOCHEMICAL PROFILE
Luminal A	RE+ and/or RP+, HER2- and ki67<14% (negative)
Luminal B	RE+ and/or RP+, HER2+ (Luminal group B HER2+)
	RE+ and/or RP+, HER2- high expression ki67 (>14%)
HER 2	RE-, RE+, HER+
Basaloid carcinoma	RE-, RP-, HER2-, CK5/6+ and EGFR+

MATERIAL AND METHODS

In this retrospective study, 281 patients admitted to the Regional Institute of Oncology Iasi and the Clinical Hospital of Obstetrics and Gynecology Cuza Voda Iasi were included, for whom the oncological records, the operative protocols of the operating room, the unique register of the service were studied; the pathological anatomy and observation sheets were considered for a period of 8 years: 2015-2022. The breast tumors was monitored according to age, place of residence, tumor size, tumor location, histopathological type, tumor grading, complications of the disease and material investigated in this study was represented by human material, respectively by breast tissue from patients. For all 281 invasive mammary carcinomas diagnosed on hematoxylin-eosin staining, they were classified into one of the corresponding histopathological types and subtypes

according to WHO criteria.

The aim of immunohistochemical study was to highlight some correlations between the cell markers Ki67, p53, HER2, hormone receptors and the histological grade, the prognosis in breast carcinomas. These pieces of surgical exeresis were fixed in formalin and initially processed by the usual paraffin embedding technique, being brought up to the paraffin block stage. The method used in the *immunohistochemical study* was one of the methods based on soluble immunoenzymatically complexes, called LSAB/HRP (*labelled streptavidin biotin*).

RESULTS

Clinical-statistical study. *The urban/rural ratio* was 1.48, urban residence being found in 167 patients. *Age* The maximum incidence of breast cancer was in the 51-60 age group and included 108 patients, representing 38.43%. The *location* of cancer in the left breast was present in 151 cases(53.73%), in the right breast it was present in 127 cases (45.19%), and bilateral breast cancer was present in 3 cases. *Signs and symptoms* The most common signs and symptoms were breast tumor in 260 patients (92.52%), homolateral axillary adenopathy in 185 patients (65.83%), carcinomatous mastitis in 19 patients (6.67%), arm edema in 11 patients (3.91%), nipple discharge in 5 patients (1.77%), bone metastases in 9 patients (3.2%), liver metastases in 8 patients (2.84 %). *The breakdown by TNM stages* was as follows: stage I was established in 9 cases (3.2%), stage II in 88 cases (31.49%), stage III in 138 cases (48.93%), stage IV was diagnosed in 31 cases (11.03%), the stage was unknown in 5.93% of patients.

Histopathological study. The histopathological study allowed, in a first stage, the classification of the 281 invasive breast carcinomas, according to the WHO classification, into one of the following types and subtypes **: 1.** invasive ductal carcinoma NOS (not otherwise specified - non-specific type of invasive ductal carcinoma) - 193 cases (68.68%)**, 2.** invasive lobular carcinoma - 42 cases (14.94%), **3.** mixed ductal-lobular carcinoma - 14 cases (5.16%), 4. Other types- 26 cases.

Immunohistochemical study. All these tumors were processed immunohistochemically and were smaller or equal to 2 cm in 98 cases and larger than 2 cm in 183 cases.

Immunolabeling analysis for hormone receptors (ER and PR). Estrogen receptors (ER) were positive (Allred score $\geq$ 3) in 61% of cases (169 patients), and progesterone receptors (PR) in 64% of cases (180 patients. Compared to the **histological type,** invasive ductal carcinomas expressed estrogen receptors in 114 cases (58.88%) and progesterone receptors in 122 cases (63.3%), while invasive lobular carcinomas expressed estrogen receptors in 34 cases (80%) and progesterone receptors in 29 cases (70%). Depending on the immunoexpression of hormone receptors, breast carcinomas are classified into four subtypes or phenotypes: **1**. 57% of cases presented both types of receptors with an ER positive/PR positive phenotype.**2**. 32% of cases were completely devoid of hormone receptors having an ER negative/PR negative phenotype. **3-4.** 11% had a heterogeneous phenotype: 7% of cases were ER negative/PR positive, 4% of cases were ER positive/PR negative.

Ki 67 immunolabeling analysis highlighted: the specific marking of Ki 67 is

nuclear and was found in 281 cases. Patients under the *age* of 50 more frequently had a high Ki67 index (over 15% of tumor cells being Ki 67 positive) compared to patients over 50 (60% of cases vs 55.55%); patients with *tumors larger* than 2 cm more frequently had a high Ki 67 index compared to those with *tumors below* 2 cm (71.42% vs 51.43%). Regarding the histological type of the analyzed carcinomas, it was found: the *lobular type* had a low Ki 67 index in all cases; the *ductal invasive type* had a low Ki 67 index in 43.87% of cases and a high index in 56.12% of cases. Related to the histological grade: high-grade tumors (G3) always had a high Ki67 index; low-grade (G1/G2) that had an increased proliferation index in only 8.62% cases.

The analysis of p53 immunolabeling identified the presence of overexpression of the p53 protein (more than 10% of tumor cells labeled with this antibody) in 99 cases (42% of the studied cases, 193 ductal carcinomas and 42 lobular carcinomas). Tumors with p53 overexpression were more frequently encountered in patients under 50 years of age (54 cases, respectively 54.55%) compared to those over 50 (45 cases, respectively 45.45%). p53 positive tumors were more frequently tumors larger than 2 cm. So, 66 tumors among the p53-positive tumors (representing 66.64% of the p53-overexpressing group) were larger than 2 cm in size, while only 33 of the p53-positive tumors (representing 33.33% of the p53-overexpressing group) were larger than 2 cm in size. smaller than 2 cm. Invasive ductal type carcinomas were p53 positive in 85 cases, representing 44.44% of all invasive ductal type cases, and invasive lobular type carcinomas in only 13 cases, representing (30%) of all type breast carcinoma cases invasive lobular Regarding the histological grade, most cases with p53 protein overexpression (73 cases, respectively 73.3%) were of high grade (G3) and only 51 cases (28.33%) had low histological grade (G1 and G2). The immunohistochemical overexpression of p53 was thus found in 46.66% of the 35 HER2 positive cases (score 2+ and 3+) and only in 96 cases (40.85%) of the 200 HER2 negative cases (score 0 and 1+). p53 overexpression (corresponding to an increased amount of p53 protein determined by IHC) was more frequent in HER2-positive breast carcinomas compared to HER2-negative ones (46.66% vs 41.17%).

The analysis of the HER 2 immunoassay allowed the highlighting of 42 cases (representing 14.94% of the studied cases) of invasive breast carcinoma positive for HER 2. Of these, 28 cases (representing 66.66%) were weakly positive (score 2+), and 14 cases (representing 33.34%) were interpreted with a score of 3+ (positive) according to the criteria (Group Biology HER2/CEP 17) Correlating the HER2 immunolabeling of tumors with their histological type, it was observed that 4 cases of lobular carcinoma (10% of lobular carcinomas were HER2 positive) were moderately HER2 positive (score 2+). All other 38 HER 2 positive cases were of ductal type (24 cases with score 2+ and 14 cases with score 3+). Thus, 15.55% of invasive ductal carcinomas were HER2 positive. Following the correlation of HER2 immunomarking with morpho-clinical parameters, it was observed that HER2 positive tumors belonged slightly more frequently to patients under 50 years of age (22 cases, respectively 52.38%) compared to those

over 50 (20 cases, respectively 47, 62%). HER2 positive tumors were more frequently tumors larger than 2 cm. Thus, 22 tumors larger than 2 cm (representing 52.38%) were HER2 positive, while 20 tumors smaller than 2 cm (representing 47.62%) were HER2 negative. Regarding the histological grade, the majority of HER2 positive cases (34 cases, respectively 80.9%) were of high grade (G3) and only 8 cases (representing 19%) had low histological grade (G1 and G2).

DISCUSSION

The clinical study was conducted over a period of 8 years, between 2015-2022 and included 281 patients with breast cancer.

Age. The maximum incidence of breast cancer was in the 50-59 age group and included 79 patients (28.11%). The older the age, the greater the risk of breast cancer. The reason for this reality seems to be related to the existence of multiple somatic mutations (multiple event theory) for breast cancer genes as the population ages (12) (tab. II).

TABLE II

Breast cancer incidence according to age (13, 14, 15, 16)

Author	Patients group	Age (years)	Incidence of breast cancer
Andrew McGuire	26 countries	50-59	71-73%
Allen S. Lichter	247	50-60	51.0%
Edward Obedian	1,029	> 50	67.9%
Coral A. Quiet	826	> 55	50.0%
Richard McQuellon	115	> 57	>50.%

Histological grading The distribution of tumors according to histological grading was as follows: histological grading G1 in 22% of cases; histological grading G2 in 50% of cases; histological grading G3 in 23% of cases. Histological grading is usually based on the criteria established by Bloom. These include tubule formation, mitoses, and nuclear characteristics (size, shape, and hyperchromatism).Black *et al Schuh* (17) divided the nuclear grades into three groups and counted them in reverse order of the histological grading: • nuclear grade1- anaplasia, • nuclear grade2- intermediate differentiation • nuclear grade3- well differentiated.

TNM staging was possible in 94.66% of cases, and in 5.93% of patients the stage was unknown. The breakdown by TNM stage was as follows: • stage I was established in 9 cases (3.2%),• stage II in 89 cases (31.49%),• stage III in 137 cases (48.93%),• stage IV was diagnosed in 31 cases (11.03%),• the stage was unknown in 5.93% of patients.

Histological study. The classification of these invasive carcinomas into the various types according to the WHO criteria demonstrated that an overwhelming number of cases (193 cases, respectively 68.51%) were represented by NOS-type invasive ductal carcinoma, these cases being followed by invasive lobular carcinoma, which was diagnosed in 42 cases, representing 14.94% of all infiltrative breast carcinoma cases studied. *Invasive*

ductal breast carcinoma NOS. It is the most common invasive breast carcinoma, representing between 40% and 75% of invasive breast carcinomas. By definition, the diagnosis of ductal carcinoma NOS is a diagnosis of exclusion, this carcinoma being a malignant epithelial tumor that cannot be classified into any of the special types of invasive breast carcinoma (20). According to the Nottingham score, NOS ductal carcinomas were classified into: NOS G1 carcinomas (48 cases - 17.08%), NOS G2 carcinomas (132 cases - 46.97%) and NOS G3 carcinomas (101 cases - 35.94 %). The separation of breast carcinomas into the 3 histological grades is arbitrary and artificial, because these tumors actually present a continuous scale of malignancy (20).

Lobular carcinoma. It was first introduced by Foote and Stewart in 1941. Invasive lobular carcinoma is the most common type of invasive breast carcinoma after invasive ductal carcinoma, accounting for 5-15% of all breast carcinomas in Europe and the United States, while in Japan this type of carcinoma represents only 1-4% of all breast cancers (21).

The classic subtype of infiltrative lobular carcinoma accounts for approximately 40% of all infiltrative lobular carcinomas (*22*). According to the Nottingham score, invasive lobular carcinomas were classified into carcinomas: G1 16 cases - 19.04%, G2 51 cases - 60.71%, G3 17 cases - 20.23%. Similar results were obtained by specialists and published in recent studies. Thus, using the criteria of the Nottingham score, classified invasive lobular carcinomas in grade 1 - 20% of cases, grade 2 - 66% of cases and grade 3 - 14% of cases and showed that the histological grade of invasive lobular carcinomas (24).

Immunohistochemical study. Hormone receptors. In this study, 61% of invasive breast carcinomas showed estrogen receptors, and progesterone receptors were detected in 64% of cases, this being in accordance with recent data from the literature that records the presence of ER in 63% of patients with invasive breast carcinoma and a PR in 65% of them (25). The majority of breast carcinomas expressed both types of hormone receptors with an ER+/PR+ phenotype (57% of cases) and were followed in frequency by tumors with absent hormone receptors and an ER-/PR- phenotype (32% of cases). Specialist studies cite that approximately 50% of invasive breast carcinomas express both types of hormone receptors, and approximately 25% lack estrogen and progesterone receptors (26). In the present study, the ER+/PR- phenotype was detected in 4% of tumors. Thus, the average level of estrogen receptors in ER+/PR- tumors is only about half that of ER+/PR+ tumors (27). The Ki-67 antigen is a non-histone protein useful for identifying proliferative cells that, not having phase specificity, is expressed in all active phases of the cell cycle (Ki-67 is not expressed in the G0 phase) (28).

Although there are currently several antibodies that can be used on paraffin sections (MM1, NCL-ki-67p, Rah Ki-67), studies show that, nevertheless, the MIB-1 antibody has the highest sensitivity, offering the best visual staining, the reproducibility of the staining index being equally good for any of these antibodies (29). Its distribution by immunohistochemical methods is limited to its appearance in the late G1 phase. Therefore, Ki-67 is recognized as an indicator of cellular mitotic

activity. An increase in Ki-67 expression indicates an increase in cellular mitotic activity and proliferation*(*30). Immunohistochemical expression of Ki 67 correlates well with growth fraction in various models and does not appear to be expressed during the DNA repair process .(31) In breast cancers, Ki67 is used to categorize patients into categories with favorable and unfavorable prognosis correlating with the clinical response to chemotherapy (32). Relative to the histological grade, high-grade tumors (G3) always had a high Ki 67 index, compared to low-grade tumors (G1/G2) which had an increased proliferation index in only 8.62% of cases. All studies that reported correlations of the KI 67 index with the histological grade of the tumors showed that tumors with a high histological grade have an increased proliferative activity compared to those with a low grade (33, 34).

The oncoprotein p53 is a phosphoprotein that has the role of "guardian of the genome", i.e., monitoring the integrity of DNA during cell division. The protein product of normal (wild-type) alleles of the p53 gene negatively regulates cell growth and proliferation, blocking cells in the G1 phase of the cell cycle. In the present study, the overexpression of the p53 protein was found in 42% of the breast carcinoma cases studied, a result well correlated with the data published in the specialized literature that vary between 16% and 48% of p53 positive cases in invasive breast carcinomas (36). Analyzing the overexpression of the p53 protein in the cases included in this study, we found that it was more frequent in patients under 50 compared to those over 50 (54.76% *vs.* 45.24%), with tumors larger than 2 cm (66.64% *vs.* 33.33). Regarding the type and histological grade of the analyzed invasive breast carcinomas, p53 overexpression was more frequently associated with the invasive ductal type compared to the lobular one (95.24% *vs.* 4.76%) and with poorly differentiated tumors (G3) compared to the well/moderately differentiated ones (28.57% *vs.* 71.43%). These results are consistent with recent studies that demonstrated that breast tumors with a high amount of p53 (measured by IHC) are significantly correlated with high histological and nuclear grade (*36*) and they are much less often lobular (37). p53 immunopositivity correlated with the absence of expression of estrogen and progesterone receptors (61.9% of cases were devoid of estrogen receptor expression *vs.* 38.1% of cases showing estrogen receptor immunoexpression) also 54.76% of cases with p53 overexpression had been negative for PR *vs.* 45.24% of positive PR cases.

Co-expression of p53 and HER 2 was found in 7% of invasive breast carcinoma cases included in this study. The rate of breast cancers that coexpress p53 and HER 2 was reported, in previous studies, as varying between 7% and 19.5% of all breast cancers examined (38).

HER2 protein. The product encoded by the HER2 gene is a transmembrane protein of approximately 185 kD that functions as a tyrosine kinase receptor, called the HER2 protein, p185 or c-erbB-2. HER2 is involved in cell differentiation, proliferation, adhesion and motility (39), occupying a key position at the level of the mitogenic signal transduction cascade both in the case of normal and tumor cells. Thus, in addition to hormone receptors, HER2 represents the most accepted prognostic and predictive factor of response or resistance

to treatment and the potential of using new treatments (Herceptin) (40).

In this study, 15% of the analyzed group's tumors were positive for HER2, of which only 5% of the cases overexpressed the HER2 protein with maximum intensity (score 3+). The overexpression rate with maximum intensity of the HER 2 protein was lower in the studied group probably due to the fact that the poorly differentiated tumors (grade G3) were much less (40%) compared to the well and moderately differentiated ones (60%). This fact supports the hypothesis that less aggressive breast tumors have a lower rate of HER2 overexpression and suggests the association between HER2 expression in the tumor and the degree of its malignancy. HER2 positive tumors were more frequently tumors larger than 2 cm. Thus, 8 tumors larger than 2 cm (representing 53.33%) were HER2 positive, while 7 tumors smaller than 2 cm (representing 46.67%) were HER2 negative. Various studies did not find an association between HER 2 overexpression and the sizes of breast tumors analyzed (41,42). Correlating the HER2 immunolabeling of tumors with their histological type found that 10% of lobular carcinomas were HER2 positive. All other HER 2 positive cases were of ductal type (with score 2+ and 3+). Thus, 15.55% of invasive ductal breast carcinomas studied were HER2 positives. Recent data suggest that HER2 overexpression is significantly more frequent in ductal than in lobular carcinomas (43).

Co-expression of HER 2 with that of ER was found in only 10.52% of breast tumors with ER+/PR+ phenotype and in 25% of breast tumors with ER+/PR- phenotype). It should be mentioned here that the presence of hormone receptors in HER positive patients does not affect the benefits of trastuzumab therapy (44).

CONCLUSIONS

The maximum incidence of breast cancer was in the 50-59 age group and included 158 patients (28.11%). The most common histological types were *invasive ductal* carcinoma in 90% of patients, *invasive lobular* carcinoma in 4.6%, carcinoma in situ in 0.8% .

The distribution by TNM stages was as follows: stage I in 9 cases (3.2%), stage II in 88 cases (31.49%), stage III in 138 cases (48.93%), stage IV in 31 cases (11.03%), the stage was unknown in 5.93% of patients. *Invasive lobular carcinomas represented, after invasive ductal carcinoma* type NOS, the most frequent (14.94% of cases) type of breast carcinoma and were presented under a very wide range of variants (classic, solid, alveolar, tubulolobular, pleiomorphic, histiocytoid and with signet ring cells). *The histological grading*. A large number of patients (101 patients representing 35.76%) were identified who presented a high histological grade (G3) correlated with a poor prognosis, compared to patients whose tumors were well differentiated (G1, 48 cases, representing 17.08%).

The subgroup of invasive breast carcinomas is that with the ER+/PR- phenotype, more frequent in patients over 50 who had tumors larger than 2 cm. The group of patients under the age of 50 presented twice as often HER2 positive tumors. Overexpression with maximum intensity of the HER2 protein is more frequently associated with poorly differentiated tumors and those without hormonal receptors. Ki67 immunostaining seems to be associated with

an unfavorable prognosis (2% of cases in the present study). Cell proliferative activity and hormone receptor status were frequent in an inverse relationship. p53 overexpression occurs most frequently in patients under 50 years of age, with tumors larger than 2 cm, of invasive ductal type and with high histological grade. The co-expression of the p53 protein with HER2 has always been associated with an extremely high proliferative activity of the respective tumors. Cases with p53 protein mutations can select a group of patients with a higher risk of recurrence and death.

PREVALENCE OF LIVER FIBROSIS AND STEATOSIS USING VIBRATION-CONTROLLED TRANSIENT ELASTOGRAPHY IN INDIVIDUALS EMPLOYED IN A NORTH-EASTERN ROMANIAN INDUSTRIAL COMPANY (Abstract): Liver cirrhosis is considered the final stage of liver fibrosis progression and the leading cause of worldwide mortality due to liver diseases. Certain liver infections, such as viral hepatitis B (VHB) and C (VHC), alcohol-related liver disease (ALD), and nonalcoholic fatty liver disease (NAFLD) were found to be significant contributors to liver cirrhosis development. The **aim** of our study was to assess the prevalence of liver steatosis and fibrosis in individuals from the industrial field in the Northeastern region of Romania. **Material and methods:** Five hundred and sixty adult asymptomatic participants, all employees of a large bakery enterprise, were selected for this study. After informed consent was obtained, the demographical, clinical, and physiological description was made for each participant. AUDIT-C questionnaire was applied to each participant. VCTE (Fibroscan) was used to measure liver fibrosis, and hepatitis virus B and C presence was screened using rapid blood tests. **Results:** We found that 56.25% of the screened participants were from rural areas, and 65.7% were male. In our study, 54.64% declared that they had a smoking history, and only 1.7% received blood transfusions in the past. Moreover, 61% of the patients had a body mass index above the normal limit, 1.7% of the participants were positive for the presence of HBs antigen, while 2.85%

exhibited HCV antibody-positive titer. During VCTE examinations, for the majority of the patients M probe was used (75.2%). Liver fibrosis was found in 33.2% of the participants, and liver cirrhosis in 8.2% of the cohort. Increased severity of liver steatosis was observed in 33.4% of the patients. **Conclusions:** By screening a cohort of apparently clinically healthy individuals residing in the Northeastern part of Romania and having different socioeconomic profiles, we observed that the frequency of advanced fibrosis is more increased, as compared to available data. **Keywords:** CHRONIC LIVER DISEASE, FIBROSIS, STEATOSIS, VIRAL HEPATITIS, ALCOHOL-RELATED LIVER DISEASE, NONALCOHOLIC FATTY LIVER DISEASE, VIBRATION-CONTROLLED TRANSIENT ELASTOGRAPHY.

Being the main cause of liver-related deaths, cirrhosis is leading to significant global morbidity and mortality and is setting a major financial burden on the healthcare systems (1). Liver cirrhosis is the final stage of liver fibrosis progression, although the prevalence of compensated cirrhosis is underreported since it presents asymptomatically in the early stages (2). Consequently, a significant proportion of people with compensated cirrhosis remains misdiagnosed until the first sign of decompensation, such as ascites, elevated bilirubin levels, variceal hemorrhage, or encephalopathy. The mortality and morbidity rates are much higher than in compensated cirrhosis, with a 1-year case-fatality rate that can surpass 80% in some situations. Nevertheless, this group of patients is typically rapidly linked to medical care (3).

Currently, chronic hepatitis B (HBV) and C (HCV) infections, non-alcoholic fatty liver disease (NAFLD), and alcohol-related liver disease (ALD) are the main causes of liver cirrhosis (4). NAFLD has emerged as the most prevalent cause of chronic liver disease worldwide, affecting about 25% of the adult population worldwide and contributing to increased global morbidity and mortality (5). This is due to the rapidly shifting landscape of the liver cirrhosis etiology as a result of effective antiviral treatments and the successful implementation of vaccination programs for viral hepatitis (6). Moreover, NAFLD is also a prominent cause of liver transplantation and a rising risk factor for hepatocellular carcinoma (HCC). Simple steatosis is regarded as the "benign form" of NAFLD, while nonalcoholic steatohepatitis (NASH), the "progressive form" with various histological features, is linked to the development of liver fibrosis, including cirrhosis and eventually HCC (5). On the other hand, alcoholism continues to be a serious health issue, with 75 million people globally having an alcohol use disorder and a high risk of ALD. ALD is a catch-all phrase that includes the alcoholic fatty liver, alcoholic hepatitis (AH), and liver cirrhosis; nevertheless, data on prevalence rates and clinical and pathological characteristics of patients with early illness are hard to come by (7). By lowering the prevalence of liver cirrhosis and associated complications, such as liver failure, HCC, and death, early diagnosis of chronic liver illnesses may improve patient outcomes while also lessening the burden of the condition. This strategy must employ simple, readily available, and economically feasible noninvasive techniques for the measurement of liver fibrosis in vast groups of asymptomatic people in order to be effective. The aspartate aminotransferase [AST]-to-platelet ratio index [APRI], the fibrosis-4 index

[FIB-4], the body mass index-AST/ALT ratio-diabetes score (BARD), the Forns score, and the NAFLD score (NAS) are a few serological markers that potentially predict future development of cirrhosis and advanced liver disease in the general population (8).

Over the years, guidelines for fibrosis evaluation have consistently supported vibration-controlled transient elastography (VCTE) as the best non-invasive approach, particularly in the case of chronic viral hepatitis. In summary, this method uses pulse-echo ultrasonic recordings to quantify the speed of a mechanically generated shear wave in a significantly larger hepatic parenchyma, with the propagation velocity being closely correlated with hepatic stiffness. This technique is frequently used in clinical settings around the world since it is quick, simple, painless, and has significant repeatability and reproducibility (9). Additionally, in recent years, the inclusion of CAP in FibroScan® (Echosens, Paris, France) equipment, which reflects the liver's fat impedance, has enabled the simultaneous evaluation of hepatic fibrosis and steatosis. Since CAP measures are a quantitative method with significant sensitivity and specificity, they enable us to detect less severe degrees of steatosis than US (10). Herein, we aimed to assess the prevalence of liver steatosis and fibrosis in individuals from the industrial field in Northeastern region of Romania.

MATERIAL AND METHODS

This study population consisted of apparently healthy individuals residing in two neighboring counties from North-Eastern Romania, all employees in the bakery industry. This geographic area is known at risk for a number of reasons, including increased exposure to risk factors like tobacco use, consumption of calorie-dense and high-fat foods, heavy alcohol intake, physical inactivity, high body mass index (BMI $\geq$ 25 kg/m^2), and restricted access to healthcare services. All participants in this study were above the age of 18, had no prior history of chronic liver disease, and gave their informed consent by signing the study's consent form. Moreover, the individuals included in our study were workers at S.C. MOPAN SUCEAVA S.A., a large bread and bakery factory, and were evaluated due to an association between Institute of Gastroenterology and Hepatology, and this company through Platform for Interdisciplinary Research, "Grigore T. Popa" University of Medicine and Pharmacy. All patients who had a history of chronic viral hepatitis HBV/HCV/ hepatitis D virus (HDV) infection or other causes of chronic liver diseases, pregnant women, individuals with cardiac pacemakers, cancer or end-stage renal diseases, or had unreliable or failed VCTE measurements were excluded. Subjects examined by VCTE were further assessed through rapid diagnostic tests to detect HBs antigen (HBsAg) and anti-HCV antibodies (HCVA): HBV (Wama Immuno-Rapid HBV®) and HCV (Wama Immuno-Rapid HCV®) and completed the AUDIT-C questionnaire to establish the alcohol consumption. The threshold that rules in subjects with excessive alcohol intake usually is 20 g per day in women, and 30 g per day in men according to recent scientific recommendations (11). Using a height meter and a weight scale, measurements of height and weight were recorded. The midpoint between the lower border of the rib cage and the iliac crest was used to calculate waist circumference using a height meter. As proxies for adiposity, the body mass

index (BMI) and waist circumference were determined. The World Health Organization established cut-off values for overweight (25 kg/m^2) and obesity (>30 kg/m^2). Abdominal obesity was defined as having a waist circumference of 80 cm or more for women and 94 cm or more for males. This measurement is frequently used as a proxy for measuring visceral adiposity (12). The Ethics Committee of our Institute approved the study activities, which were conducted in conformity with the Declaration of Helsinki's guiding principles. Before the examination, all subjects gave their free and informed consent.

The FibroScan 520 Compact device (Echosens, Paris, France) was used for the VCTE and CAP procedures. It is outfitted with the M (regular probe - transducer frequency 3.5 MHz) and XL (transducer frequency 2.5 MHz) probes. An experienced doctor who has performed more than 300 examinations conducted each one in accordance with the procedure's instructions (13). The liver fibrosis stages were identified by the following cut-off values: mild fibrosis 5.6 kPa, considerable fibrosis 8.0 kPa, advanced fibrosis 9.6 kPa, and cirrhosis 13 kPa; LSM results were expressed in kilopascals (kPa) ranging from 1.5 to 75 kPa; The degree of steatosis was separated by the following cut-offs: mild steatosis 274 dB/m, (moderate steatosis) 290 dB/m, and severe steatosis 302 dB/m. CAP was expressed in decibels/m, with a range of 100 to 400 dB/m (9).

The *SPSS* software (version 22.0, IBM SPP Inc., Chicago, IL, USA) was used to perform the statistical analyses. Quantitative variables were expressed as means ± standard deviation (SD), whilst qualitative data were expressed as numbers and/or percentages (%). For distribution analysis, the Kolmogorov-Smirnov test was applied. The student's t-test, Mann-Whitney U test, or chi-square test were deemed suitable for comparing group variables. The Pearson correlation coefficient (r) was used to determine the relationship between two variables. Statistical significance was defined as two-tailed p-values 0.05.

RESULTS

In total, 560 individuals had been screened when the call for participants came to an end. Their median age was 48.14 ± 7.9 years, and 65.7% of them were male. Most of them were from rural area (56.25%). Professional school was the most common achieved educational level (43.9%), followed by high school and junior high school levels (30% and 16.8%, respectively). Only 9.3% of the population had the elementary school level in this regard. 306 (54.64%) of respondents said they had ever smoked cigarettes. 7.7% of the population said they have ever received blood transfusions. Also, among them 43.58% were positive for AgHBs and anti-HCV antibodies. On the other hand, 159 (28.4%) of patients reported consuming alcohol. In this cohort the prevalence rate of type 2 diabetes mellitus was 20.4%. 293 patients (52.3%) had high blood pressure, and 47.1% of individuals had dyslipidemia. Regarding body weight, our participant population was distributed as follows: six individuals (1.1%) were underweighted, 212 participants (37.9%) were normal weight, 207 participants (36.9%) were overweight, and 135 participants (24.1%) were obese. The mean BMI value for our cohort was 27.09 ± 3.12 kg/m^2. Also, 23 (4.1%) patients were AgHbs positive, and 16 (2.85%) detectable HCV antibody titer (tab. I).

TABLE I.
Baseline characteristics of studied population

	Overall Cohort N = 560
Age (years)	48.14 ± 7.9
Males, n (%)	368 (65.7)
Weight	79.26 ± 16.11
Height	169.48 ± 9.83
Body mass index (kg/m^2)	27.09 ± 3.12
Underweight, n (%)	6 (1.1)
Lean subjects, n (%)	212 (37.9)
Overweight, n (%)	207 (36.9)
Obesity, n (%)	135 (24.1)
Hypertension, n (%)	293 (52.3)
Dyslipidemia, n (%)	264 (47.1)
Alcohol intake, n (%)	159 (28.4)
HBV, n (%)	23 (4.1%)
HCV, n (%)	16 (2.85%)
History of type 2 diabetes mellitus, n (%)	114 (20.4)
Smoking history, n (%)	306 (54.64)
Blood transfusion, n (%)	43 (7.7)
Education, n (%)	
Elementary school	52 (9.3)
Junior high school	94 (16.8)
High school	168 (30)
Professional school	246 (43.9)

Regarding VCTE examinations, M-probe was utilized in 421 (75.2%) participants whereas a XL probe was employed in 139 (24.8%) subjects. Eight people failed the measurement, or 1.42% of the population under the study. The cut-offs used for liver fibrosis were as follows: F0, when LSM < 5.6 kPa, F1, when LSM = 5.6 – 7.9 kPa, F2, when LSM = 8 – 9.5 kPa, F3, when LSM = 9.7 – 12.9 kPa, and F4, when LSM ≥ 13 kPa. According to fibrosis stage, most of the patients had F2 level of liver fibrosis (33.2%). 161 (28.8%) individuals have no fibrosis, and 46 (8.2%) of patients have cirrhosis. The mean value of LSM was 7.2 ± 5.03 kPa. The following were the hepatic steatosis cut-off values: S0 - < 274 dB/m, S1 – 274 – 289 dB/m, S2 – 290 – 301 dB/m, S3 - ≥ 302 dB/m. Regarding steatosis degree, 33.4% of subjects have severe steatosis, with mean CAP value of 278.35 ± 67.82 dB/m (tab. II).

TABLE II.
Characteristics of VCTE examinations

Characteristics	**Mean ± SD or number (%)**
Probe size	
M	421 (75.2)
XL	139 (24.8)
Steatosis degree (dB/m)	
CAP < 274 (dB/m)	122 (21.8)
CAP ≥ 274 (dB/m)	148 (26.4)
CAP ≥ 290 (dB/m)	103 (18.4)
CAP ≥ 302 (dB/m)	187 (33.4)
CAP (mean ± SD) (dB/m)	278.35 ± 67.82
Fibrosis stage (kPa)	
LSM < 5.6 kPa	161 (28.8)
LSM ≥ 5.6 kPa	102 (18.2)
LSM ≥ 8 kPa	186 (33.2)
LSM ≥ 9.6 kPa	65 (11.6)
LSM ≥ 13 kPa	46 (8.2)
LSM (mean ± SD) (kPa)	7.2 ± 5.03

History of alcohol consumption, and presence of chronic viral hepatitis (HBV or HCV) were linked with risk for developing severe liver fibrosis (≥ F3) (r = 0.27, p = 0.04) and (r = 0.36, p < 0.001) (fig. 1). High values of BMI and the presence of type 2 diabetes mellitus were correlated with increased CAP values among our cohort (r = 0.17, p = 0.021) and (r = 0.27, p = 0.03) (fig. 2).

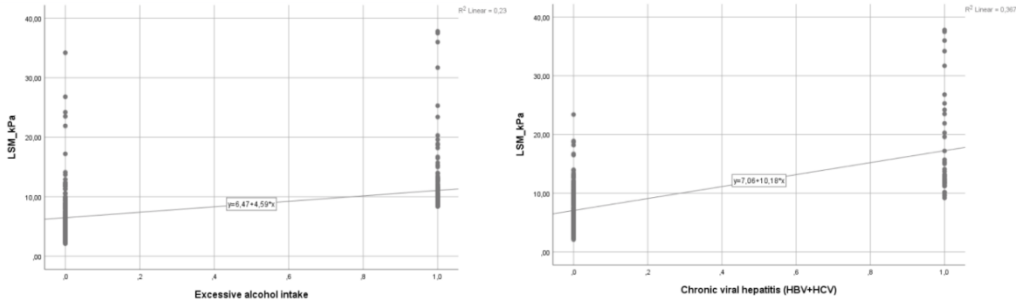

Fig. 1. Correlation between LSM and (A) excessive alcohol intake, (B) chronic viral hepatitis

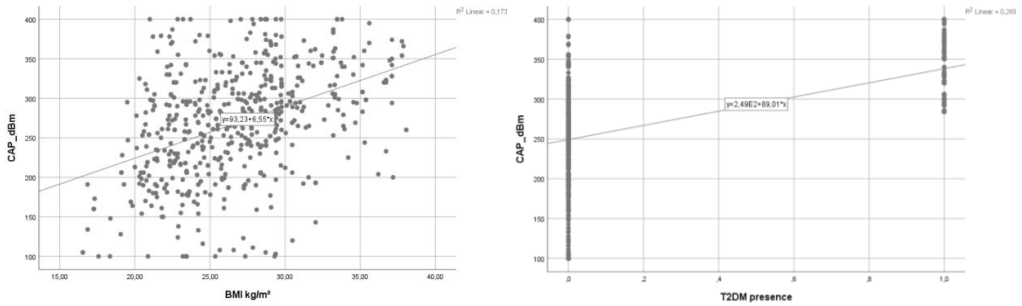

Fig. 2. Correlation between CAP and (A) BMI values, (B) presence of type 2 diabetes mellitus

DISCUSSION

There is a significant financial burden on healthcare systems as a result of liver cirrhosis, which ranks as the 7th most common cause of high disability-adjusted life years and the 11th most common cause of mortality worldwide. The most recent epidemiological research indicate that Europe appears to have the highest global burden of liver disease, and alarming predictions regarding an increase in cases over the next several years are being made (14). The World Health Organization most recent statistics from 2018 show that 8,763 people died in Romania from liver disease, or 3.75% of all deaths. Romania is ranked 47th in the world by age-adjusted death rate, which is 26.90 per 100,000 people. According to data from the Romanian National Institute for Public Health, liver cirrhosis accounted for 34.6 deaths per 100.000 people in 2019 and was the primary cause of mortality in digestive illnesses. With more than 20 deaths per 100,000 people, Lithuania and Hungary both had high mortality rates, at half in comparison with Romania (15).

The analyses of data subsets deriving

from the National Health and Nutrition Examination Survey (NHANES) 2017-2018 revealed that NAFLD had a prevalence of 58.5% and that US fatty liver index (US-FLI) is a reliable scoring system dedicated to diagnosing patients with fatty liver diseases. However, a drawback is that it requires a complementary calculation of insulin levels, for which the odd ratio (OR) was 4.97 in contrast with the indexes for hepatic steatosis (HSI), ORs = 21.2, and fatty liver (FLI) ORs = 18.6 (16).

Another study brought forward both positive and non-significant correlations following CAP and LSM through VCTE assessment of serum uric acid (UA) and marijuana use, whilst no relationships were identified in cases of urinary metabolite concentrations of di-2-ethylhexyl phthalate (DEHP) and vitamin D deficiency. Precisely, Duan *et al.* (17) further emphasize an overall OR of 2.097 and 2.983 and consistence in a sex-matched subgroup, whereas Du *et al.* (18) was able to highlight a low prevalence of steatosis is past ($p = 0.184$) and current users ($p = 0.048$). Recently, Shen *et al.* (19) successfully advanced weight-adjusted-waist index (WWI) to predict hepatic steatosis, WWI suggesting a strong association with hepatic steatosis ($p < 0.0001$) and not liver fibrosis ($p = 0.84$), but extrapolating in relation to excessive alcohol consumption ($p = 0.031$) and hypertension ($p = 0.014$) as multivariate linear regression analysis indicate.

On the other hand, Chen *et al.* (20) failed to observe a significant relationship between liver fibrosis and phthalates for LSM ≥ 8 kPa, but rather in the fourth quartile for mono-(2-ethyl-5-carboxypentyl) phthalate and mono (2-ethyl-5-hydroxyhexyl) phthalate of which the ORs were 2.719 ($p = 0.016$) and 2.073 ($p = 0.037$). This argument of a lack of association extends to the research conducted by Ji *et al.* (21) because the serum vitamin D had a linear trend regardless of participants' group allocation (74.26 *vs.* 72.24 nmol/L for which $p = 0.21$), nor discovered through multivariate logistic regression analysis, instead being uncovered a lower liver fibrosis risk for an OR of 0.89 for a deficiency of vitamin D in NAFLD patients.

Complementary investigations in the field advanced the possibility of enhancing the diagnostic accuracy and thus two teams found out that CAP and LSM identified with an area under the receiver operating characteristic curves (AUROCs) of 0.87 and 0.83 of patients with steatosis, fibrosis and 0.93 those with cirrhosis for the following intervals: 0.77 for S ≥ S1, and S2, and 0.70 for S = S3 at Youden cutoff values of 302, 331, and 337 dB/m, and 0.77 for F ≥ F2, 0.80 for F ≥ F3, and 0.89 for F = F4, respectively, with also Youden cutoff values of 8.2, 9.7, and 13.6 kPa compared with 6.5/12.1 kPa to exclude advanced fibrosis (AF) and cirrhosis at negative predictive values of 0.91 and 0.99. Moreover, a positive predictive value (PPV) of 0.71 and 041, LSM may identify patients with AF and cirrhosis (22, 23). Previous studies from Romania, which were published recently found that in a group of medical students, the prevalence of steatosis and advanced fibrosis was 17.4% and 0.7% respectively, in apparently healthy individuals. Instead, among individuals with type 2 diabetes mellitus the prevalence of advanced fibrosis and cirrhosis was 11.7% and 13.6% respectively (24, 25).

Poverty and chronic liver diseases are linked, due to a variety of factors, such as a higher risk of using tobacco products, eating calorie-dense, high-fat foods, being physically inactive, being overweight or obese, and having less access to healthcare. People who lived in poverty have a higher

mortality rate after being diagnosed with a chronic illness in every country. It's been thought of as rather paradoxical because the poor in middle- and high-income countries tend to be more obese than the wealthy. The same risk factors like in some Romania counties were present in Latin America or Asia, particularly in low- and middle-income nations like Mexico, where the average BMI is approximately 27 kg/m^2, 65% of the population is overweight or obese (BMI $\geq$ 25 kg/m^2), and 26% of the population is obese (BMI $\geq$ 30.27 kg/m^2). Cirrhosis will be one of the most preventable diseases causing death worldwide since it is predicted that the number of deaths worldwide from non-communicable diseases in lower-middle income nations would rise from 13 million in 2005 to approximately 19 million in 2030.

Our study had some limitations. First off, as we included apparently healthy individuals and, no histology data on people with advanced liver fibrosis or cirrhosis were taken due to the lack of liver biopsy. Another drawback is that there was no follow-up to assess if the therapies had changed the CAP score or the LSM, and to maintain monitoring of long-term impacts.

CONCLUSIONS

The assessment of advanced fibrosis by VCTE in a population with particular socioeconomic profile indicates a higher frequency of advanced fibrosis than is apparent in the data available from North-Eastern Romania. In this demographic, obesity is regarded as a separate risk factor for advanced fibrosis. To establish preventive interventions in this demographic area, more research is required.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest.

PREDICTIVE SCORES FOR HEPATOCELLULAR CARCINOMA OCCURRENCE AFTER HEPATITIS C VIRUS CURE WITH DIRECT ANTIVIRALS (Abstract): Hepatitis C virus (HCV) chronic infection has an important tumorigenic propensity and represents a major cause of hepatocellular carcinoma (HCC). Although the therapy of chronic HCV infection has been revolutionized with the introduction of direct acting antivirals (DAAs) resulting in sustained virological response (SVR) in up to 98% of patients, viral clearance does not totally alleviate the risk of liver-related complications, including HCC. The **aim** of our study was to assess the performance of predictive scores for HCC occurrence in patients with chronic HCV infection who obtained SVR with DAAs. **Material and methods:** We conducted a prospective study in which we included 992 patients diagnosed with chronic HCV infection and treated with DAAs, between 1st November 2015 and 31st December 2020. HCC risk scoring systems were applied to each patient enrolled in the study before starting DAA treatment. HCC was diagnosed by imaging methods such as computed tomography and magnetic resonance imaging. **Results:** Of the 992 patients included in the study, 59 (5.9%) were diagnosed with HCC during the follow-up period, mostly women (55.9%) with a mean age of 60-69 years. The mean time to HCC onset was 19.53 ± 11.553 months, with a median of 17 months, with a cumulative incidence at 1, 3, and 5 years of 1.1%, 2.1%, and 2.9%, respectively. The General Evaluation Score (GES), aMAP and ADRESS score had statistically significant higher values in patients with HCC than in those without HCC. GES demonstrated a good discriminating power with an AUC coefficient of 0.804 at a cut-off value of 6.25 which has good sensitivity and specificity (0.746 and 0.799, respectively). **Conclusions:** GES score has a very good predictive power for the risk of HCC after obtaining SVR and could be recommended in clinical practice. Future development and validation of other individualized predictive scores score is needed for a correct and cost-efficient selection of patients with high risk of HCC. **Keywords:** CHRONIC HEPATITIS C INFECTION, DIRECT-ACTING ANTIVIRALS THERAPY, HEPATO-CELLULAR CARCINOMA, PREDICTIVE SCORES.

Hepatitis C virus (HCV) chronic infection has an important tumorigenic propensity and represents a major cause of hepatocellular carcinoma (HCC). Although the therapy of chronic HCV infection management has been revolutionized with the introduction of direct acting antivirals (DAAs), resulting in sustained virological response (SVR) in up to 98% of patients, viral clearance does not totally alleviate the risk of liver-related complications, including HCC (1). Still, there is strong evidence that SVR significantly improves the prognosis in patients with chronic HCV infection by lowering the risk of liver cirrhosis, decompensation and HCC, irrespective of whether it was achieved by using interferon-based regimens or DAAs (2). The high efficacy and availability of DAAs worldwide determined a rapidly growing of the SVR-patients pool, and thus it seems reasonable to consider strategies for a correct stratification of HCC risk.

The main tools for early diagnosis of HCC are screening strategies, which should accomplish the main goal of cancer surveillance that is the decrease of cancer specific mortality at cost-effective terms (3). In line with this, the current guidelines have different recommendations for HCC surveillance in those with SVR. The European Association for the Study of the Liver (EASL) considers the presence of F3 fibrosis and cirrhosis before start of treatment as an indication for HCC surveillance (4), whereas the American Association for the Study of Liver Disease (AASLD) takes into account only those with cirrhosis (5). Interestingly, the recommendations from the Asian Pacific Association for the Study of the Liver does not rely on fibrosis stages and recommends HCC surveillance in all patients with SVR (6). However, it is important to take into consideration the cost-effectiveness of HCC surveillance which is mainly determined by an accurate estimation of the incidence and thus by a correct stratification of HCC risk after SVR. There are numerous studies that evaluated several stratification tools regarding HCC risk in patients with HCV clearance, but data is still scarce (7,8).

In this study, we aimed to assess the performance of several predictive scores for HCC occurrence in patients with chronic HCV infection who obtained SVR with DAAs.

MATERIAL AND METHODS

Study design and study population

We conducted a prospective study in which we included 992 patients diagnosed with chronic HCV infection and treated at the Institute of Gastroenterology and Hepatology in Iasi, between 1st November 2015 and 31st December 2020. All patients met the following inclusion criteria: (1) age over 18 years; (2) diagnosis of HCV infection with detectable HCV-RNA; (3) no contraindication of DAAs therapy; (3) without previous diagnosis of HCC. All patients from the study cohort were followed up until February 1st , 2022.

Clinical and laboratory data

Patients enrolled in the study were followed-up prospectively by clinical-biological and imaging monitoring from study inclusion until 1st February 2022. Demographic variables for the enrolled study population included age and sex. Cirrhosis was defined as the presence of any of the following findings: coarse liver echotexture and nodular liver surface by ultrasonography, clinical features of portal hypertension (e.g., ascites, splenomegaly, or varices), or thrombocytopenia (<150,000/mm3).

Laboratory data included anti-HCV, aspartate and alanine aminotransferases, bilirubin, alkaline phosphatase, Gama glutamyl transpeptidase, albumin, international normalized ratio, prothrombin time, serum creatinine, hemoglobin, platelet count, and alpha-fetoprotein levels. Serum HCV RNA levels were measured in all patients before and at 3 months after the end of treatment (COBAS TaqMan HCV quantitative test (Roche Molecular Systems, Inc. Branchburg, NJ). Transient elastography (FibroScan; Echosens, Paris, France) was used to perform the liver stiffness measurement (LSM) with 13 kPa as the cutoff point for cirrhosis.

Diagnosis of HCC

The diagnosis of HCC was established based on current guideline recommendations using abdominal US as the initial method (4). In case of ultrasound detection of a nodule larger than 1 cm, the diagnosis was confirmed by a more sensitive method such as CT or MRI, and if the result was inconclusive, the following imaging method was used, liver biopsy being reserved for cases uncertain at 2 successive investigations.

Predictive scores

HCC risk scoring systems were applied to each patient enrolled in the study before starting DAA treatment.

The General Evaluation Score (GES) comprises 5 variables scored each as follows: (1) gender: women 0 points, men 3.5 points; (2) age: ≤54 years 0 points, >54 years 1 point; (3) degree of fibrosis: F3 1.5 points, F4 3 points; (4) albumin: ≥ 3.8g/dL 0 points, <3.8g/dL 2 points; (5) AFP: ≤20 ng/ml 0 points, > 20 ng/ml 3 points. The total score can reach a maximum value of 12.5 points and allows placing the patient in one of 3 risk groups: low ≤6, intermediate risk >6 - 7.5, and high risk >7.5.

The aMAP score was calculated using the formula ({0.06 x age + 0.89 x sex (male:1, female: 0) + 0.48 x [(log10 bilirubin x 0.66) + (albumin x −0.085)] - 0.01 x platelet count} + 7.4) / 14.77 x 100. Based on the score, the patients were divided into 3 groups: low risk < 50 points, intermediate between 50 and 60 points, high > 60 points.

The ADRESS-HCC score was calculated based age, presence of type 2 diabetes, race, etiology of cirrhosis, sex and severity of liver disease. Depending on the score obtained, patients were divided into 3 groups: low risk (corresponding to quartile 1), intermediate (quartile 2-3) and high (quartile 4).

Statistical processing was carried out using *Microsoft Excel* and *SPSS version 28* (Inc., Chicago, IL) software. Survival curves were estimated by the Kaplan-Meier method and compared, for univariate analysis, by the log rank test. To evaluate the discriminatory ability for the prediction of HCC, we evaluated the accuracy of prediction for each scoring system. This point was evaluated calculating the area under the receiver operating characteristic (ROC) curve for each staging system.

The study was carried out in accordance with the ethical principles of the Declaration of Helsinki, the protocol being explained in detail to all patients. Informed consent for participation in the study was obtained from all patients and/or their relatives.

RESULTS

Of the 992 patients included in the study, 59 (5.9%) were diagnosed with HCC during the follow-up period, mostly women (55.9%) with a mean age of 60-69 years. The mean time to HCC onset was 19.53 ±

11.553 months, with a median of 17 months; the shortest period of time was 3 months and the longest 51 months. Of the total of 59 patients with HCC, only 6 of them (10.2%) were diagnosed within an interval shorter than 6 months, in the remaining 53 (89.8%) the diagnosis was established after more than six months. Thus, the cumulative incidence at 1, 3, and 5 years was 1.1%, 2.1%, and 2.9%, respectively.

According to the GES score, the vast majority of patients were in the low-risk class (76.6%), followed by the intermediate-risk class (14.5%), the fewest being in the high-risk class (8, 9%) (fig. 1). On the other hand, according to the aMAP interpretation, 60.7% of the patients were in the high-risk category, 33.5% in the intermediate risk category, and only 5.7% of the patients belonged to the low-risk category (fig. 2). Regarding the ADRESS score, 25% of patients had values less than 5.0565 (Q1), 50% had < 5.5557 (Q2) and 25% had > 5.9608 (Q3) (fig. 3).

The comparative analysis of GES, aMAP and ADRESS risk scores in patients with HCC versus those without HCC showed that the score values were significantly higher in patients with HCC (fig. 4).

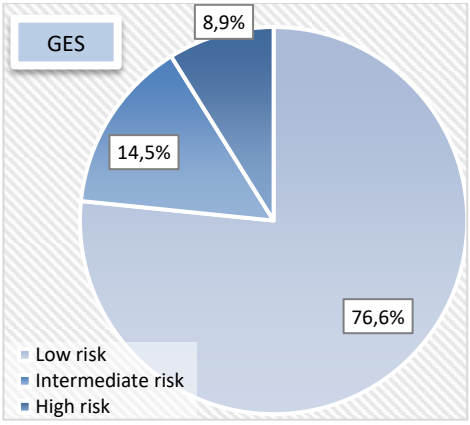

Fig. 1. Risk classes according to GES

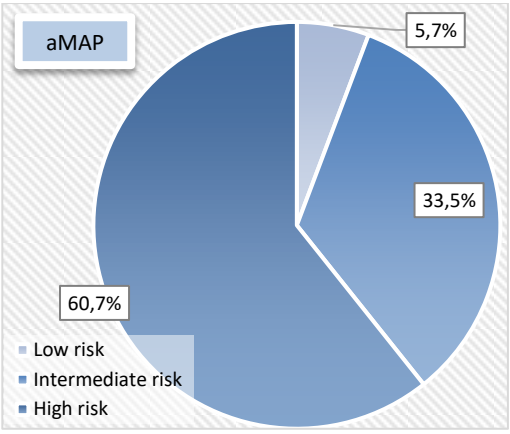

Fig. 2. Risk classes according to aMAP

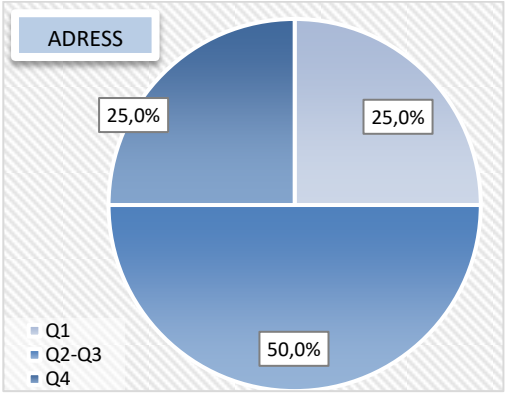

Fig. 3. Risk classes according to ADRESS

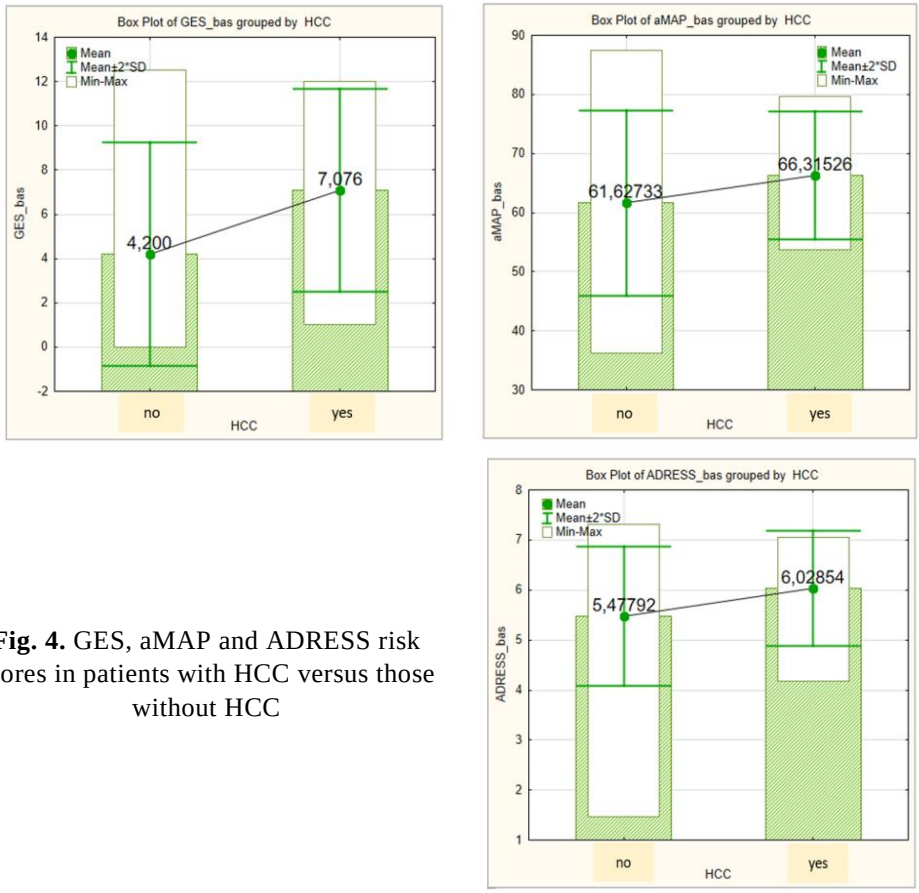

Fig. 4. GES, aMAP and ADRESS risk scores in patients with HCC versus those without HCC

Next, we performed the ROC analysis of the prediction scores, with the aim of identifying their discrimination potential (by evaluating the AUC surface) and the optimal cut-off values (with the best sensitivity-specificity combination) (tab. I).

TABLE I.

ROC analysis of the prediction scores for HCC

	AUC (Area under Curve)	p	Confidence interval 95%		Cut-off value	Sensitivity	Specificity
			Lower limit	Upper limit			
GES	0.804	0.000	0.748	0.860	6.25	0.746	0.799
aMAP	0.700	0.000	0.638	0.761	64.57854	0.737	0.650
ADRESS	0.743	0.000	0.681	0.805	5.6571	0.797	0.599

Only GES had the AUC coefficient greater than or equal to 0.8 - which corresponds to a good or excellent discriminating power for the investigated situation, namely the risk of HCC. The identified cut-off value of 6.25 has both reasonably good sensitivity and specificity. The corresponding ROC curve is illustrated in figure 5.

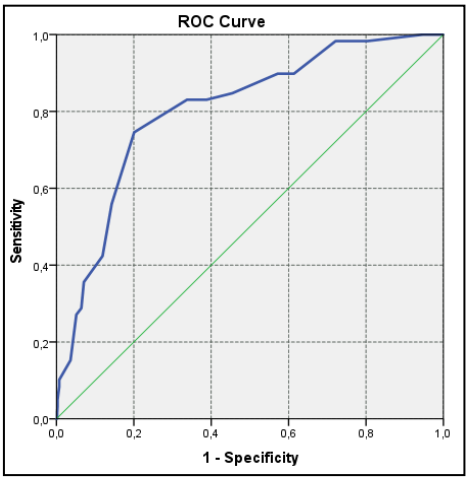

Fig. 5. ROC curve for GES

DISCUSSION

HCC risk scoring systems in patients with chronic HCV hepatitis are derived from prediction models used for chronic HBV hepatitis. Interest in these predictive systems has increased with the introduction of the new DAAs into the therapeutic management of patients with chronic HCV infection. In the pre-DAA era, when limited therapeutic options were reflected in the proportion of viremic patients, scoring systems were developed to expand or narrow the surveillance indications for HCC.

Research in recent years that identified the major risk factors involved in the occurrence of HCC, led to the development of numerous predictive scores, some externally validated and with a very good predictive value, such as the GES score, aMAP and ADRESS. Consequently, one of the aims of this study was to determine the effectiveness of these scores in predicting the risk of HCC after achieving SVR with AAD. Of the 3 scores, only the GES score had excellent discriminatory power for HCC risk at a cut-off value of 6.25 (AUC coefficient: 0.804). Indeed, the GES score was the only one of the 3 whose derivation cohort consisted of patients with chronic HCV infection treated with DAAs (9). However, in contrast to our results, the performance of the GES score was suboptimal in another recent study including 577 patients with HCV infection and liver cirrhosis who achieved SVR with the new DAAs (10). The authors' conclusions were that the GES score failed to correctly discriminate HCC risk, one of the reasons being that the demographic characteristics of the Caucasian patients included in this cohort are different from those of the Egyptian patients in the derivation cohort. However, it should be kept in mind that the results of this study are limited by the small number of patients included.

The aMAP and ADRESS scores, on the other hand, were derived from cohorts of patients with hepatopathies of various etiologies (11,12). The results in the case of the ADRESS score were more satisfactory compared to the aMAP score, but it did not have a good enough discrimination ability to accurately predict the risk of HCC ac-

cording to the 3 risk groups (the AUC coefficient in the case of the ADRESS was 0.743 versus 0.700 in the case of aMAP). Similarly, in a recent study conducted by Shiha *et al.*, the aMAP score failed to predict the risk of HCC in 2085 patients with chronic HCV genotype 4 infection and fibrosis grade F3 and F4 after achieving SVR with AAD (13).

In contrast, other studies evaluated composite HCC risk scores, which were based on combinations of multiple variables, to stratify patients into different HCC risk classes. Four studies focused only on patients with advanced fibrosis or cirrhosis, by proposing a combination of patient-related (age, sex, presence of DM) and biochemical (albumin, GGT, platelet count, AFP) variables, together with data related to by the severity of the liver disease (14,15). Abe *et al.* recently reported that the risk factors for HCC identified in multivariate analysis were pre-SVR serum albumin level for non-cirrhotic chronic HCV infection patients and ALBI score, platelet count and DM for CH patients (14).

CONCLUSIONS

Our study showed that GES score has a very good predictive power regarding the risk of HCC after obtaining SVR and could be recommended in clinical practice for the identification of high-risk patients suitable for surveillance. Future development and validation of other individualized predictive scores score is needed for a correct and cost-efficient selection of patients with high risk of HCC.

CONFLICT OF INTEREST AND FUNDING

The authors declare no conflict of interest.

THE USEFULNESS OF NEUTROPHIL-TO-LYMPHOCYTE RATIO FROM THE BRONCHO-ALVEOLAR LAVAGE (BNLR) IN THE ASSESSMENT OF PATIENTS WITH INTERSTITIAL LUNG DISEASE (Abstract): The present study **aims** to evaluate the usefulness of neutrophil-to-lymphocyte ratio from the bronchoalveolar lavage (bNLR) in the assessment of local inflammatory status in patients with the stable interstitial lung disease by comparing a group of patients with IPF *versus* non-IPF patients. A secondary outcome was to see if we can identify values that differentiate idiopathic pulmonary fibrosis from another interstitial lung disease. **Materials and methods:** 42 patients with newly diagnosed ILD (24 with IPF and 18 non-IPF) were included; physical examination, high resolution CT, bronchoscopy with lavage, spirometry, DLCO and blood tests were performed in all patients. **Results:** We did not find any statistically significant difference between bNLR in the two groups IPF *versus* non IPF. bNLR were similar 2.73 + 1.14 in the non-IPF group and 2.98 ±1.72 in IPF patients, p=0.59. bNLR in patients with chronic stable newly diagnosed interstitial lung disease does not seem to bring any additional information. **Conclusions:** Assessment of local lung inflammation in BAL by the bNLR variable can provide minimal differential diagnostic information with higher values in IPF and HP. **Keywords:** NEUTROPHIL-TO-LYMPHOCITE RATIO, BRONHCOALEVOLAR LAVAGE, INTER-STITIAL LUNG DISEASE.

The diagnosis of interstitial lung disease (ILD) is a challenging task and very frequent, despite all efforts, a decisive conclusion cannot be made. The bronchoalveolar lavage (BAL) is part of the assessment of ILD and according to ATS/ERS guidelines, it is recommended when there is no typical UIP appearance on HRCT or if there is a

high degree of uncertainty regarding diffuse interstitial pathology (1). The decision to perform BAL, however, must be analyzed from patient to patient as performing bronchoscopy with BAL can trigger an exacerbation with worsening of the general condition and increased mortality. Serum neutrophil-to-lymphocyte ratio (sNLR) is already a validated marker of systemic inflammation and has been studied in numerous respiratory, infectious, neoplastic, cardiovascular, and autoimmune diseases (2-6). In interstitial lung disease sNLR can be used to assess inflammatory status, disease severity, and short-term prognosis (7,8,9). It has been shown that an sNLR value of 2.8 in patients with non-exacerbated interstitial lung disease is suggestive of systemic inflammation (3). Most studies evaluated NLR from the blood and there have been few studies that have assessed NLR values and its implication in BAL. Data in the literature appraising BAL in patients with ILD follow cell populations rather than NLR value itself, focusing on the identification of exacerbations. Thus, in ILD exacerbations, a high neutrophil count (>25%) and low lymphocyte count (<20%) appear to be associated with a negative prognosis (10). Given the paucity of existing data regarding NLR from bronchoalveolar lavage and the complexity and difficulty of diagnosis in ILD, we attempt to assess the applicability of NRL in current diagnostic practice. The present study aims to evaluate the usefulness of neutrophil-to-lymphocyte ratio from the bronchoalveolar lavage (bNLR) in the assessment of local inflammatory status in patients with stable newly diagnosed interstitial lung disease. Our hypothesis was that if NLR can be used in evaluating inflammation in the blood, it would help evaluate local inflammation and eventually be used to discriminate between various ILDs considering its values, for example IPF versus non-IPF group.

MATERIALS AND METHODS

Study design: it is a prospective cohort study conducted between 2018- 2019 in the "Leon Daniello" Clinic Hospital of Pulmonology, from Cluj-Napoca. **Study population**: 42 patients, over 18 years old with newly diagnosed interstitial lung disease. Exclusion criteria: history of neoplasia, regardless of location; association of known chronic obstructive pulmonary diseases; known genetic disease, diagnosis of pneumoconiosis, or a history of pulmonary tuberculosis, acute infectious disease; patients who received antibiotic treatment 14 days prior to admission, regardless of cause, severe respiratory failure requiring NIV; severe cardiovascular disease; documented psychiatric disease or non-compliant patients. All the patients signed the informed consent. ILD diagnosis was made according to current guidelines after clinical evaluation, imaging, BAL, and multidisciplinary meeting. Bronchoscopy was carried out by the same physician during hospitalization. The analysis of the lavage was performed by the same laboratory physician according to the currently existing good practice guidelines immediately after it was collected, within the first 30 minutes. From the BAL, total cell count and percentage of recovered cells were assessed according to the standard analyzer. By simple rule of 3, from the total cellularity, the absolute value for lymphocytes and neutrophils was calculated to perform the neutrophil/lymphocyte ratio (bNRL). Patients were further divided into two groups those with idiopathic pulmonary fibrosis (IPF) and those with other ILDs

(non-IPF). The non-IPF group included patients with hypersensitivity pneumonitis, sarcoidosis, and undifferentiated ILDs. Spirometry and TLCO were performed at the time of admission according to the ERS/ATS recommendations (11,12). FEV1%, FVC%, TLCO% were noted. The value of DLCO was divided, into 4 groups: 1 > 80%, 2: 50 - 80%, 3: 30 - 50%, and 4 < 30%. The study was approved by the Ethics Commission of the Faculty of Medicine and Pharmacy number 345/1.10.2019 and was reapproved by the Ethics Commission of the Clinical Hospital of Pneumphtysiology "Leon Daniello", Cluj-Napoca 4/2020. Statistical analysis was performed with IBM SPSS v20.0 (Armonk, NY, USA) for Windows. TI-Nspire CX CAS Graphing software is used to perform all statistical analyses and to create all graphical displays.

RESULTS

Forty-two patients with confirmed interstitial lung disease were included in the study: 24 in the IPF group and 18 in the non-IPF group. The bNLR value found was 2.73 + 1.14 in the non-IPF group and 2.98 ±1.72 in IPF patients, p=0.59. No statistically significant differences were found between respiratory function and simple cellularity found in BAL (neutrophils, lymphocytes) in the two groups analyzed (tab. I).

There is no statistically significant difference in bNLR between the two IPF versus non-IPF groups on 0.237 (fig. 1). There is a moderate/weak linear negative correlation r= -0.503 between bNLR value and lung function in IPF patients. The higher the NLR, the lower the lung function (fig. 2). When referring to DLCO there is a weak correlation r=0.302 (fig. 3).

If smokers were removed, the correlation coefficient r increases to -0.575 for FVC and 0.399 for TLCO, suggesting a correlation between them separately from smoking status (figs. 5 and 6). In the non-IPF group no correlation was found between NLR from lavage and lung function assessed by FVC or DLCO.

TABLE I.

Patients functional and blood parameters

	Groups	Number	Median	Standard	Standard	p-value
Neutrophils	non-IPF	18	4.26	2.18	0.51	0.29
	IPF	24	5.01	2.32	0.47	
Lymphocytes	non-IPF	18	1.73	0.77	0.18	0.65
	IPF	24	1.82	0.63	0.13	
NLR	non-IPF	18	**2.73**	**1.14**	0.27	**0.59**
	IPF	24	**2.98**	**1.72**	0.35	
FVC (%)	non-IPF	18	77.78	13.90	3.28	0.18
	IPF	23	71.32	16.08	3.35	
FEV1/FVC	non-IPF	18	77.03	13.24	3.12	0.87
	IPF	23	77.64	11.80	2.46	
FEV1 (%)	non-IPF	18	76.27	20.04	4.72	0.73
	IPF	23	74.23	18.05	3.76

DISCUSSION

The present study assessed the utility of NLR from bronchoalveolar lavage (bNLR) in the evaluation of inflammatory status of patients with stable chronic ILDs (IPF versus non-IPF). No difference was found

between the two groups, bNLR was 2.73 ±1.14 in the non-IPF group and 2.98 ±1.72 in the IPF group, p=0.65. According to our study it is not possible to use bNLR to differentiate between the two groups, as it's the case with serum NLR (3). Studying bNLR in patients with IPF and other fibrosing interstitial lung diseases (PH and sarcoidosis) D'Alessandro and colleagues have identified a statistically significant higher bNLR values in patients with IPF compared to non-IPF group, 2.1±3.8 (IPF) *versus* 0.7±1.9 (sarcoidosis) and 1.6±3.1 (PH) (13). Increased bNRL values were found before severe exacerbation of ILD, frequently associated with an unfavorable outcome (13). A higher bNRL value has also been proposed as an independent risk for lung cancer based on the involvement of inflammation in oncogenesis (13). And this is an important aspect as patients with ILDs are at risk of developing lung cancer that might be undiagnosed in the begging due to extensive parenchymal involvement in some interstitial lung disease (14). Animal studies have shown an increase bNLR in relation with the progression of pulmonary lesions suggesting that bNLR might be an indicator of the severity of lung involvement (15). Concerning threshold values in differentiating different ILD, bNLR showed a sensitivity of 56% and a specificity of 96% for confirmation of PH, when bNRL > 0.48. In the present study the values for both groups were the same, probably as a consequence small sample size and inhomogeneity of the non IPF groups. In healthy nonsmoking individuals BAL contains 85% macrophage, 10-15% lymphocytes and less than 3% neutrophils. Increases or decreases in these percentages have been correlated with different pathologies, but integrated analysis of cellular ratios could increase diagnostic accuracy (16). In patients with ILD at the time of diagnosis and during exacerbation there was an increased percentage of lymphocytes and/or neutrophils in the lavage regardless of the type of ILD (10). The low lymphocyte percentage and high neutrophil percentage (increased bNLR) were independent negative prognostic factors for 90-day survival (10). The above-mentioned study only emphasizes the probability that there is an as-yet poorly understood interconnection between bNRL and lung lesion extension. Similar results were also obtained by Salonen in a study of 20 patients in whom BAL was performed both at baseline and during an AE-ILD. BAL cell count < 20% lymphocytes or > 20% neutrophils during AE-ILD was associated with shorter survival (17). Since bNLR is the neutrophil/lymphocyte ratio in absolute value, we can extrapolate the information and say that bNLR was increased more during exacerbations or even before exacerbations. Concerning bNLR as a predictor of mortality in patients with fibrotic PH and IPF phenotype Barrat *et al.* (18) conclude that increased NLR values are associated with poorer survival in patients with IPF. In ILD patients, a negative prognostic marker remains the reduction in lung function. bNLR appears to correlate weakly/moderately with lung function only in patients with IPF and not in the non-IPF group. So, we can suspect a relationship between lung inflammation as assessed by bNRL and lung volume reduction with a possible prognostic role. Limitations of the study: the small sample of patients, the lack of control group (healthy individuals) and the inhomogeneity of the non-IPF group

comprising various pathologies with different cell profiles. However, it is one of the few studies evaluating bNLR from bronchoalveolar lavage in patients with stable diffuse interstitial lung disease at first diagnosis (*so naïve patients*). But ultimately the question remains whether it is worth the risks of a post-FB exacerbation to assess NLR. Unfortunately, our study, given the small number of patients, cannot transcribe this answer now.

CONCLUSIONS

Assessment of local lung inflammation in BAL by the bNLR variable can provide minimal differential diagnostic information with higher values in IPF and HP. Interestingly enough bNRL shows higher values in the idiopathic disease group, which further supports the inflammatory theory in the pathogenesis and maintenance of IPF. The inflammatory marker bNRL negatively correlates with lung function suggesting the implications of inflammation in lung volume reduction. These findings integrated into broader future research may optimize the management and follow-up of patients with ILD.

NON-INVASIVE TOOLS TO PREDICT FIBROSIS IN METABOLIC DYSFUNCTION-ASSOCIATED STEATOTIC LIVER DISEASE (MASLD). THE RESULTS OF THE PROSPECTIVE STUDY FROM THE HEPATOLOGY TERTIARY CENTER FROM IASI **(**Abstract): Metabolic dysfunction-associated steatotic liver disease (MASLD) previously known as non-alcoholic fatty liver disease (NAFLD), represents nowadays the most common cause of chronic liver disease. The gold-standard method for assessing the degree of steatosis and fibrosis is liver biopsy (invasive method). The aim of the study was to establish the role of non-invasive testing (serological and imagistic) in identifying MASLD patients at higher risk to develop advanced fibrosis. **Materials and methods**: a total of 111 patients with MASLD was tested for fibrosis using non-invasive tests. Serological test that were used consisted in the NAFLD fibrosis score (NFS), Fibrosis Index for liver fibrosis (FIB-4) and BARD. Imagistic method consisted in 2D shear wave elastography (2D-SWE.GE elastography). **Results:** The majority of patients (54.9%) had significant fibrosis (F2-F4). The degree of liver fibrosis assessed by 2D-SWE.GE elastography could have been correlated with a range of serological parameters. Liver transaminase values were, in the majority of subjects, the only changes detected. The increase was moderate, and the ASAT/ALAT ratio was subunit. We found statistically significant differences between subgroups of patients with and without advanced fibrosis in the following parameters: BMI, platelets, albumin, blood glucose. All three types of testing identified the cases with significant fibrosis. NFS testing correlated best with advanced fibrosis estimated from 2D-SWE.GE elastometry. **Conclusions:** Serological and imagistic tests are validated tools to predict advanced fibrosis in MASLD patients. The limitation of the study is the relatively small number of patients and the lack of reporting on liver biopsy. **Keywords**: METABOLIC DYSFUNCTION-ASSOCIATED STEATOTIC LIVER DISEASE (MASLD), SEROLOGICAL MARKERS, 2D SHEAR WAVE ELASTOGRAPHY.

Metabolic dysfunction-associated steatotic liver disease (MASLD) previously known as non-alcoholic fatty liver disease (NAFLD), represents nowadays the most common cause of chronic liver disease (1, 2). With a global incidence ranging be-

tween 6% and 35%, MASLD is more prevalent in the more developed Western countries (2, 3). The term MASLD encompasses a broad spectrum of different stages of liver damage, ranging from steatosis and metabolic steatohepatitis (MeSH) to MASLD-related cirrhosis and even hepatocellular carcinoma (2, 4). The risk factors for MASLD include waist circumference, blood pressure, plasma triglycerides, plasma high-density lipoprotein-cholesterol, prediabetes, homeostasis model assessment of insulin resistance score, and plasma high sensitivity C-reactive protein. The combination of hepatic steatosis with one of these three metabolic risk stratifications results in the diagnosis of MASLD (5). When assessing the degree of steatosis and fibrosis, the gold standard method is represented by liver biopsy. A number of non-invasive tests (serological markers and imagistic methods) have been developed for replacing the need of a liver biopsy. The aim of the study is to establish the role of the non-invasive testing (serological and imagistic) in identifying MASLD patients at higher risk to develop advanced fibrosis.

MATERIALS AND METHODS

Prospective study, with a group of 111 patients with MASLD (82 male, 29 female patients), aged between 26 and 77 years old (mean age 54.92 years old; p=0.104). The group of patients were registered at the Gastroenterology and Hepatology Institute, of the "Sf. Spiridon" County Clinical Emergency Hospital Iasi. The diagnostic was established from clinical, biological and ultrasound data. Evaluation of each patient consisted in its medical history, clinical exam, laboratory blood testing and 2D-SWE.GE elastography. Including criteria were age over 18 years old, established diagnosis of chronic liver disease (for a minimum of 6 months), MASLD classified. Patients also had to agree to take part in the study and perform all necessary testing. Excluding criteria consisted in pregnancy, lack of discernment (hepatic encephalopathy), chronic liver disease from other causes (B hepatic virus, C hepatic virus, autoimmune disease, alcoholic disease, toxic, drug induced, hemochromatosis, Wilson disease), patients with heart failure, inflammatory bowel disease, intestinal resection, thyroid disease, vascular malformation, focal hepatic lesion on ultrasound, medication that influences portal flow (beta blockers for example). Non-invasive serological tests were the NAFLD fibrosis score (NFS), Fibrosis Index for liver fibrosis (FIB-4) and BARD. The included imagistic method was the 2D shear wave elastography (2D-SWE.GE elastography). NAFLD fibrosis score (NFS) uses 6 variables (age, BMI, blood glucose, platelet count, serum albumin, ASAT/ALAT ratio), and was calculated online. A value <-1.455 has a 90% sensitivity and a 60% specificity in excluding advanced fibrosis, while a score >0.676 has a 67% sensitivity and a 97% specificity for identifying advanced fibrosis (6). Between these values, a "gray area" occurs, in which the diagnosis is uncertain. Fibrosis Index for liver fibrosis (FIB-4) uses parameters like age, ASAT, ALAT and platelet count. Advanced fibrosis is excluded at a score value of <1.30, whilst a score >2.67 confirms the diagnosis. A limitation of this method consists in the existence of indeterminate area between the values. BARD is a test based on ASAT/ALAT ratio, BMI and the presence of diabetes. A value of 0 or 1 has a high negative predictive value (96%) for advanced liver fibrosis (7), while a score ≥2 has a high sensibility for detecting advanced fibrosis, but with a modest specificity (8). 2D-SWE.GE elastography was performed using

a C1-6-D convex probe in Elasto 2D-SWE.GE mode. Liver rigidity (LS) expressed with Young Module (kPa) was saved for each image and automatically calculated. For test validation, the IQR (Inter Quartile Range)/median value ratio must not exceed 30%. The used cut-off values were <6.6 KPa (F0-F1), 6.6-7.9 KPa (F2), 8-10 kPa (F3), >10.1kPa (F4), as proposed by Kim *et al.* (9). Statistical data analysis was made using descriptive statistics and inferential analysis (analytical). Were applied Shapiro-Wilk normality test, t-Student, Chi Squared Test and Spearman's rank correlation coefficient for comparative analysis between samples.

RESULTS

We evaluated the correlation between non-invasive tests (NFS, FIB-4, BARD) with the fibrosis degree evaluated by 2D-SWE.GE elastography. Elastometry value distribution is presented in tab I. Mean values of NFS, FIB-4 and BARD testing are presented in tab. II. In tab. III and tab. IV we present the results of the comparative study of non-invasive diagnosis testing, respectively of post-hoc testing in relation with fibrosis degree. Statistically significant differences were shown between 2 patient groups with different fibrosis degree, F0-F1 versus F3-F4 and F2 versus F3-F4 (p=.000*).

TABLE I.

Distribution of liver stiffness (kPa) in the group of patients with MASLD

Figures 1, 2 and 3 shows the mean values obtained from the 3 non-invasive tests (NFS, FIB-4, BARD), for each fibrosis degree. We evaluated the correlation degree between the 3 non-invasive tests. We looked especially for the correlation between risk values and fibrosis degree F3-F4 (advanced fibrosis). The results are shown in tables V, VI and VII.

In the study group, the NFS test made the best correlation with the patient's advanced fibrosis, with a high sensitivity (90.3%) for the diagnostic of advanced fibrosis. However, we must notice the low specificity (46.2%) of the test. According to our results, the second-best test for diagnostic accuracy is the BARD test, which has an 87.1% sensitivity and a modest 41.3% specificity. The FIB-4 test registered the lowest diagnostic sensibility (41.9%), but with a 73.8% specificity, better than NFS and BARD tests.

DISCUSSION

Most of the patients from the study group (54.9%) had important fibrosis (moderate and severe F2-F4). One explanation for these results is that these patients came to a tertiary hepatology center. The patients with mild steatosis or a small degree of fibrosis are observed in outpatient regime, at the level of primary medicine. Aim of our study was to obtain and study the risk value distribution of clinic and biologic parameters from patients with MASLD. Our results are consistent with literature data. When referring to noninvasive serological tests, the only modified values in most patients in our study group were hepatic transaminases (ASAT, ALAT). The values were moderately elevated (up to 1 to 4-fold the normal value), and the ASAT/ALAT ratio was subunit. The same serological profile is indicated also in other studies (10, 11). However, some studies show that a normal transaminase value does not guarantee the absence of steatohepatitis or advanced fibrosis (11). We evaluated the relationship between fibrosis degree and the values of the used parameters. There were statistically significant differences between the subgroups with and without important fibrosis when referring to the following parameters: BMI, platelet count, albumin, blood glucose levels. These observations are in accordance with literature data (12-15). We consider that the statistic results regarding the correlation between investigated parameters (noninvasive serological and elastometry) and fibrosis degree are relevant because are made from a high enough number of patients in our study group. The relationship between serological parameters and elastometry value shows statistical relevance. Correlation regarding fibrosis, separated for each fibrosis degree, were

affected by the small patient group. For the platelet count parameter, we obtained a single relevant statistic correlation for each fibrosis degree. One possible explanation for the fact that other parameters do not correlate is the small number of patients in one subgroup. The results are in accordance with literature data, which validate the use of elastometry as a non-invasive diagnostic method of advanced liver fibrosis (16). Monitoring the patients with MASLD using non-invasive testing represents a topic of interest because of the risk to develop advanced fibrosis. Non-invasive serological and imagistic testing are useful tools for a quantitative estimation of the fibrosis degree, as shown in numerous studies (6, 16-21). In our study, we put our effort in verifying the specificity and sensibility of three noninvasive serological tests (NFS, FIB-4, BARD), in relation with results from imagistic noninvasive testing (2D-SWE.GE elastography). Numerous studies show that NFS testing and FIB-4 are valid for evaluation of fibrosis degree in patients with non-alcoholic fatty liver disease and non-alcoholic steatohepatitis. Two studies from 2015 and 2018 evaluated the severity of steatosis, inflammatory status and degree of fibrosis in a group of 36 patients with non-alcoholic fatty liver disease (diagnostic on ultrasound) using non-invasive testing SteatoTest, ActiTest and FibroTest (22, 23). The authors concluded that non-invasive testing is useful for detection of advanced fibrosis in patients with steatosis on ultrasound, for the selection of patients for liver biopsy and for monitoring disease evolution and treatment efficiency. One meta-analysis regarding the prediction ability for severe fibrosis, included 4 studies, with a total number of 1038 of adult patients and compared data from the studies that investigated the three non-invasive tests that we also used in our study (NFS, FIB-4, BARD) (19). The research investigated sensibility and specificity using Spearman's rank correlation coefficient. Prevalence of severe liver fibrosis among patients in all 4 studies was 13%. For the FIB-4 test, sensibility value was 0.844 and a specificity of 0.685, with a threshold value of 1.30. When raising the threshold value to 3.25, sensibility value decreased to 0.38 and specificity value raised to 0.96. Regarding BARD score, sensitivity value was 0.74, specificity 0.66, significantly lower compared to the FIB-4 testing. The conclusion of the meta analysis was that the FIB-4 test with a threshold value of 1.30 present the highest diagnostic accuracy, better than with a threshold of 3.25 and then NFS, BARD testing (19,20). Similar results were also reported by McPherson *et al.* (21), who compared the diagnostic performance of some non-invasive tests (also including NFS, FIB-4 and BARD) in a study group of 145 patients with NAFLD. In this study, FIB-4 score presented the highest diagnostic accuracy for severe fibrosis (0.86), followed by ASAT/ALAT ratio (AUROC 0.83), NFS (AUROC 0.81), BARD (AUROC 0.77) and ASAT values (AUROC 0.67). A common and important aspect of the mentioned studies is represented by the fact that liver biopsy can be avoided in more than a half of the cases with NAFLD by using non-invasive testing (ASAT/ALAT ratio, FIB-4, BARD testing). The results obtained from our study regarding the diagnostic accuracy of non-invasive tests are different from literature data. All three tests identified the cases with significant fibrosis. Separated analysis showed that NFS test correlated the best with advanced fibrosis

estimated by 2D-SWE.GE elastometry. For our study group, NFS test correlated best with advanced fibrosis, with a sensitivity of 90.3%, but with a rather low specificity of 46.2%. The following test in order of diagnostic accuracy was BARD testing, with a sensitivity of 87.1% and a modest specificity of 41.3%. FIB-4 testing presented the lowest sensitivity (41.9%), but with the highest specificity (73.8%), better than the other tests. We also mention that the FIB-4 test recorded the lowest share of false positive results (26%), lower than the other 2 tests. In contrast with the mentioned studies, we haven't used liver biopsy for identifying advanced fibrosis, instead we used elastometry. We correlated the results of non-invasive serological testing with imagistic testing. We consider that as a possible explanation for the discordant results. The prevalence and incidence of patients with MASLD in daily practice shows the need to develop new, non-invasive, cost-efficient, reproducible methods for monitoring and management of those patients. Considering the raised number of patients with MASLD there is a higher need for developing a diagnostic algorithm and a higher demand for using prediction markers with good replicability.

CONCLUSIONS

In our study group we managed to correlate the presence of fibrosis degree (evaluated with 2D-SWE.GE elastometry) with a series of biological parameters (serological tests NFS, FIB-4, BARD). For our group, all three tests identified the cases with advanced fibrosis. Separate analysis showed that NFS test correlated best with advanced fibrosis estimated with 2D-SWE.GE elastometry. Serological and imagistic tests are validated tools to predict advanced fibrosis in MASLD patients. The limitation of the study is the relatively small number of patients and the lack of reporting on liver biopsy.

CONFLICT OF INTERESTS AND FUNDING

The authors declare that there is no conflict of interest and they received no specific funding regarding this scientific research.

DIAGNOSTIC APPROACHES AND MANAGEMENT OF DEEP NECK SPACE INFECTIONS (Abstract): Deep neck infections (DNI) represent critical medical conditions involving the deep cervical spaces and demand urgent and precise diagnostic measures to prevent severe complications such as airway obstruction, mediastinitis, and sepsis. Accurate and early diagnosis is paramount for effective management and improved patient outcomes. The study has in mind an analysis that provides a component for the efficiency of the medical act and resources, in order to optimize diagnostic strategies and to prevent the occurrence of sepsis. **Materials and methods**: An observational analytical retrospective study was conducted on a group of 110 patients selected from January 1, 2016 to December 31, 2022. **Results**: The most frequent clinical presentation was the infection of the lateral cervical space, the frequency of cases being 61 (55.45%), followed by the parapharyngeal and prevertebral locations 24 (21.82%). Considering the laboratory investigations, the white blood cell count was above the normal value with a mean of 15410.1 (SD: 5455). Positive culture was obtained from 61 patients (55.45%). Isolated aerobic bacteria were isolated in 29 (48.3%), gram positive aerobic bacteria were identified in 38 (34.55%), and Gram-negative aerobic bacteria in 8 (7.27%). Nonbacterial culture was observed in 47 patients (42.73%). All 110 patients received intravenous broad-spectrum antibiotics, which were subsequently upgraded based on culture and sensitivity report. Complications were encountered in 46 patients (41.82%). Airway Obstruction was presented by 24 patients (21.82%), and Mediastinitis was found in 31 patients (28.18%) (tab. III). The average number of days of hospitalization in the hospital was 17.3 days (SD: 10.49), and it varied between 2 days and 51 days. **Conclusions**: Success in the therapy of deep neck infections lies in early and accurate diagnosis, appropriate use of antibiotics, timely surgical intervention when necessary and a multidisciplinary approach to care. This ensures effective infection control and minimizes the risk of complications, ultimately improving patient outcomes. **Keywords**: DEEP NECK SPACE INFECTIONS.

INTRODUCTION

Deep neck infections (DNI) are infections in the potential spaces and fascial planes of the neck with abscess formation or cellulites (1). These involve the deep spaces of the neck and are bacterial infections originating in the upper aero digestive tract. DNI represents pathology with multiple implications, being a major surgical emergency with rapid evolution towards complications that, if not treated timely, can lead to death (2).

The incidence of this disease was relatively high before the advent of antibiotics, requiring prompt recognition and early interventions (3). Odontogenic infection is one of the most common causes, especially in developing countries (4). Clinical manifestations of DNI depend on the spaces involved and include pain, fever, malaise, fatigue, swelling, odynophagia, dysphagia, trismus, dysphonia, otalgia, and dyspnea (5, 6).

Descending necrotizing mediastinitis is the most feared complication and results from retropharyngeal extension of infection into the posterior mediastinum. Septic shock is associated with a mortality rate of 40-50% (7, 8). In addition, suppurative thrombophlebitis of the internal jugular vein associated with pulmonary septic embolism, cavernous sinus thrombosis, and carotid artery erosion have been reported (9).

Management of deep cervical infections includes prompt diagnosis, antibiotic therapy, airway management, and surgery. The therapeutic approach is traditionally based on prompt surgical drainage of the abscess followed by antibiotics or non-surgical treatment using appropriate antibiotics in the case of cellulites (10). Proper diagnosis and prompt management can effectively overcome the disease and provide a cure without complications. However, for this to be possible, otolaryngologists must have a good insight into the presentation, etiology, investigations, and access to appropriate medical and surgical interventions (11, 12).

The aggressiveness of this pathology with a mortality of 20-25%, which can reach 40% of cases through mediastinal extension, requires multidisciplinary, Otolaryngology, oral and maxillofacial treatment, thoracic surgery, anesthesia and intensive therapy (13, 14). These infections are frequently polymicrobial, with a symbiotic relationship between aerobic and anaerobic bacteria (15). Streptococci, *Peptostreptococcus species*, *Staphylococcus aureus* and anaerobes are the most commonly cultured organisms in DNI (16). Many authors recommend urgent drainage, as the infection from cervical abscesses can easily spread and have life-threatening complications such as acute obstruction of the upper respiratory tract, mediastinitis, sepsis, even death (16, 17).

The aim of our study was to present the experience of the Otolaryngology and Oromaxillofacial Departments of the "Sf. Spiridon" County Clinical Emergency Hospital in Iasi, Romania regarding clinical aspects, involved locations, bacteriology, management and complications in deep neck infections. The study focuses on an analysis that provides a component for the efficiency of the medical act and resources, in order to optimize diagnostic strategies and to prevent the occurrence of sepsis.

MATERIALS AND METHODS

An observational analytical retrospective study was conducted on a group of 110 patients selected from January 1st, 2016 to December 31st, 2022. Patients included in

the study were hospitalized for deep throat infection, surgical and medical treatment. The medical data recorded in the patients' electronic records were processed, alongside appropriate imaging (computed tomography and intraoperative photo images). The study was approved by the Clinical Research Ethics Committee at the "Sf. Spiridon" County Clinical Emergency Hospital in Iasi, Romania 15/03/2021.

Inclusion criteria comprised of hospitalized patients who were diagnosed with deep throat infection; with bacteriological examination performed; CT examination and who required surgery.

Exclusion criteria included patients with fistulized or incised peritonsillar phlegmon without affecting the deep cervical spaces, patients with infections in the cervical region that did not require surgical interventions, as well as patients with fistulized intra-oral abscesses.

The identification and documentation of the cases considered the existing changes at the cervico-facial level, the associated lesions and associated pathology, etiology, imaging investigations, treatment method, time elapsed from the diagnosis to the surgical intervention, follow-up in the dynamics of postoperative healing, the complications, surgical reinterventions to avoid the extension of the infection to mediastinum.

The following parameters were analyzed: patient age, sex, antibiotic therapy before admission, imaging and radiological investigations, symptoms, comorbidities, location of infections, treatment, intraoperative findings, bacteriological culture results, complications, length of hospitalization. Abscess locations were divided into 6 regions: submandibular and retrostylian, parapharyngeal and prevertebral. lateral cervical, anterior cervical, retropharyngeal and cervical mediastinitis. All patients were operated under general anesthesia. All 101 patients received IV antibiotic therapy. The choice of antibiotic drugs was decided according to the patient's age, comorbidities and whether he had previously received antibiotic treatment. Antibiotic treatment was reviewed based on culture results and patient response. The selected antibiotics were: cefort and gentamicin or with amoxicillin and clavulanic acid; amoxicillin and clavulanic acid with clindamycin; meropenem, clindamycin and vancomycin +/- colistin; ceffort and clindamycin; cefort and metronidazole.

Microbiology cultures were obtained for all 110 patients for both aerobic and anaerobic agents. The identification of pathogens in the first 24-48 hours was carried out by bacteriological examination of secretions from the abscess, taken by puncture or from the surgical wound. To identify the germs, the MALDITOF device was used, the antibiograms were performed on cards on Team Freedom Evo. Results were checked after the institution of the treatment according to the antibiogram to see if negative.

Statistical Analysis. The statistical analysis of data was performed using a *SPSS version 29* statistical package program. Descriptive statistics of the analyzed variables were performed. Continuous variable was reported as mean values and standard deviation (SD) or median with 25th–75th percentiles (range), depending on the normality and homogeneity of the data series. The Kolmogorov–Smirnov test was applied to verify the normal distribution of the variables. The qualitative variables were presented as absolute (n) and relative (%) frequencies, and the comparison among the groups was based on the results of the

Pearson chi-square test. The significance level calculated in utilized tests (p-value) was considered for the values of $p < 0.05$.

RESULTS

In the "Sf. Spiridon" County Clinical Emergency Hospital in Iași, Romania between January 1st, 2016 and December 31st, 2022, 1,921 patients were treated in the departments of Otolaryngology and Oro-maxillo-facial. According to the inclusion and exclusion criteria mentioned in the material and method section, 110 patients with deep neck infections (DNI) were included in the study. The analysis of patient characteristics indicated a large predominance of male patients (74.55%). Their average age in the analyzed group was 53.77 (standard deviation: 15.3).

Considering the laboratory investigations, the white blood cell count was above the normal value with a mean of 15410.1 (SD: 5455). The mean values and standard deviations of the results of laboratory investigations are presented in table I. The mean C reactive protein (CRP) level was 25.58 mg/L, and the mean blood sugar level was 125.8 mg/dL. There were 34 patients with diabetes (30.91%) (tab. I).

The most frequent clinical presentation was the infection of the lateral cervical space, the frequency of cases being 61 (55.45%), followed by the parapharyngeal and prevertebral locations 24 (21.82%) (tab. I). The most common etiology in our study proved to be the pharyngo-tonsillar localization of the infection, constituting 52.7% of cases. Sore throat 81 (73.64%) and dysphagia were the most common symptoms 84 (76.36) (tab. I).

Comorbidities were found in 52.73% of patients (58 cases). Very frequently they were associated, 82.3% of patients presented two or more associated comorbidities (tab. I). Diabetes mellitus was found in 30.91% of cases (34 patients), and cardiovascular diseases were reported in 35.45% of cases (39 patients). Cardiovascular disease included coronary heart disease or other prior myocardial disease, congestive heart failure, prior stroke, or transient ischemic attack. Immunocompromised status was also found in 20.19% of cases (23 patients) and malignant tumors in 3.64% of cases (4 patients). In the group of immunocompromised patients, we included patients receiving drugs for autoimmune diseases or other known immunodeficiencies. Alcohol excess was mentioned in the patient's history in 5.45% of cases (6 patients) (tab. I).

Positive cultures were obtained from 61 patients (55.45%). Isolated aerobic bacteria were isolated in 29 (48.3%), gram positive aerobic bacteria were identified in 38 (34.55%), and Gram-negative aerobic bacteria in 8 (7.27%). Nonbacterial culture was observed in 47 patients (42.73%) (tab. II).

All 110 patients received intravenous broad-spectrum antibiotics, which were subsequently upgraded based on culture and sensitivity report. Complications were encountered in 46 patients (41.82%). Airway obstruction was presented by 24 patients (21.82%), and Mediastinitis was found in 31 patients (28.18%) (tab. III). The average number of days of hospitalization in the hospital was 17.3 days (SD: 10.49), and it varied between 2 days and 51 days (fig.1).

There was no significant relationship between length of hospitalization and patients' comorbidities ($p = 0.0874$). Also, the statistical analysis did not reveal a statistically significant relationship between the hospitalization time and the location of deep neck infections. ($p = 0.0791$).

TABLE I.

Baseline characteristics of the patients with deep neck infections

Characteristics	Group study,n=110 cases
Gender, male / female, n (%)	82 / 28 (74.55 / 25.45)
Age, years, mean (SD)	53.77 (15.13)
Blood test	
Leukocytes, mm^3, mean (SD)	15410.1 (5455)
C-reactive protein, mg/L, mean(SD)	25.28 (9.04)
ESR (erythrocyte sedimentation rate), mean (SD)	49.2 (16.75)
Fibrinogen, mg/dL, mean (SD)	595.6 (98.8)
Presepsin, pg/m, mean (SD)	527.2 (114.4)
Blood sugar, mg/dL, mean (SD)	125.8 (57.7)
Neutrophil ratio (%)	81.2 (13.5)
Creatinine (µmol/L)	76.9 (11.6)
Location	
submandibular and retrostylian	15 (13.64)
parapharyngeal and prevertebral	24 (21.82)
lateral cervical	61 (55.45)
anterior cervical	17 (15.45)
retropharyngeal	14 (12.73)
cervical mediastinitis	21 (19.09)
Etiology factors	
odontogenic infections	9 (8.18)
pharyngo-tonsillar infections	58 (52.73)
epiglottis	16 (14.55)
foreign body	3 (2.73)

DISCUSSION

Recent studies indicate that the incidence of DNI has not significantly declined despite advances in antibiotic therapy, likely due to increased rates of antibiotic resistance and the prevalence of comorbid conditions such as diabetes mellitus and immunosuppression (18). Common pathogens include *Streptococcus species*, *Staphylococcus aureus*, MRSA, and anaerobic bacteria. The rise in odontogenic infections as a primary source of DNI has also been noted, suggesting the need for improved dental care and early intervention for dental abscesses (19).

Computed tomography (CT) with contrast remains the gold standard for diagnosing DNI, offering detailed information on the extent of the infection and the presence of abscesses. Magnetic resonance imaging (MRI) has shown promise in specific scenarios, such as when evaluating potential complications like vascular involvement or when CT results are inconclusive (20). Ultrasound has gained traction for initial evaluations and guiding needle aspirations, particularly in pediatric populations (21).

Empirical broad-spectrum antibiotic therapy remains a cornerstone in managing DNI, with regimens typically including coverage for both aerobic and anaerobic bacteria. Studies highlight the increasing importance of tailoring antibiotic therapy based on culture results to combat antibiotic resistance effectively (22).

There is ongoing debate regarding the necessity of surgical intervention in all cases of DNI. Recent data suggests that in selected cases, particularly with smaller abscesses (<3 cm), conservative management with antibiotics alone may be sufficient (23). However, surgical drainage

remains essential for larger abscesses and when there is imminent risk of airway compromise or progression to mediastinitis. Minimally invasive procedures, such as CT-guided needle aspiration and endoscopic drainage, have been increasingly utilized and show promise in reducing the morbidity associated with traditional open surgical procedures. These techniques are particularly useful for patients with significant comorbidities who may not tolerate more invasive surgery (24).

Recent literature highlights the high risk of complications associated with DNI, including airway obstruction, mediastinitis, and septic shock (25). Early intervention remains critical in preventing these severe outcomes. The role of corticosteroids in reducing inflammation and preventing airway compromise is being explored, with some studies indicating potential benefits in selected patients (26).

Management of DNI in pediatric populations requires special consideration due to anatomical and immunological differences compared to adults. Studies emphasize the importance of conservative approaches and the judicious use of imaging and surgical interventions to minimize long-term sequelae in children (27).

Deep neck infections are serious and potentially life-threatening conditions that require prompt diagnosis and effective management. They involve the potential spread of infection in the deep spaces of the neck, which can lead to severe complications such as airway obstruction, sepsis, and mediastinitis (28).

Identifying the profile of the patient with deep throat infection allows doctors to provide appropriate and timely treatment to manage the infection. Prompt airway protection for patients with deep neck infections and mediastinitis is extremely important. Upper airway obstruction and subsequent respiratory failure require emergency tracheostomy. Effective management of the deep neck infections requires a multidisciplinary approach involving otolaryngologists, infectious disease specialists, radiologists, and critical care teams to address both the infection and its potential complications (29).

Deep neck infections occur in the potential spaces and fascial planes of the neck. The management of such infections typically involves the use of diagnostic imaging, such as CT scans or MRI, to accurately locate and determine the extent of the infection. Treatment generally includes a multidisciplinary approach engaging various specialists like otolaryngologists, infectious disease experts, head and neck surgeons, radiologists, microbiologists, and intensive care specialists (30).

The primary aims of treatment are to control the infection and prevent complications. This often involves surgical intervention to drain any abscesses and debride necrotic tissue. Antibiotic therapy is essential and typically broad-spectrum to cover a variety of bacteria until specific pathogens can be identified. In advanced cases, reconstructive surgery or tissue grafts may be necessary to repair or replace tissues damaged by the infection (31). Continuous research and advancements in head and neck reconstructive techniques are crucial for improving long-term outcomes and restoring both function and appearance for patients following a deep neck infection (32).

In order to reduce the duration and costs of hospitalization, we propose dynamic evaluation of bacteriological examinations, of local evolution through serial computer

tomography examinations, as well as establishing the moment of surgical intervention (tracking the number of days that elapse from hospitalization to the surgical procedure (33). Information regarding the sequencing in the dynamics of biological and imaging parameters will contribute to the safety of the therapeutic act. The retrospective, but especially prospective, follow-up study will bring information on bacteriological variability, which will contribute to preventive therapeutic strategies (targeted antibiotic therapy) for severe complications (IJV thrombophlebitis, sepsis).

Deep abscesses of the cervical region are of major importance due to their frequency and severe complications. Similarly, with Singhal *et al*., 2022, our studies observed a higher incidence in the young male population (34).

However, Huang *et al*. and other studies also show an upward trend in the incidence of infections in elderly patients and patients with systemic diseases. In this group, defense mechanisms would be less effective, recovery rates would be slower and complications would be more frequent (35).

In the pre-antibiotic era, pharyngeal, tonsillar infections were responsible for 70% of deep throat infections (36).

Currently, many studies show a significant decrease in incidence, with odontogenic infections being the most common cause. In our study, bacterial tonsillitis was the most common cause (31.68%), followed by odontogenic infection (23.7%), totaling 55.3% of our samples (37).

In a study by Kusumoto *et al*., the dental focus was the origin of the most frequent abscesses in 37% of patients, while pharyngeal tonsils and disorders were present in 20% of cases, not being possible to identify the source of infection in 33% of patients (38). For Sennes *et al*. odontogenic infection was the cause in 42.1% of patients, tonsillitis in 17.5%, post infections of the upper airways in 15.8% and unknown cause in 8.8% lymphadenitis (39).

Other authors have also reported a significant proportion of deep cervical space infections of unknown primary origin, reaching up to 50% of cases (40).

In 14.8% of our patients, the etiology infection could not be determined, probably because the initial infection was not promptly diagnosed, although it preceded the abscess. Thus, the average time from symptom onset to diagnosis in our study was 8 days, but it was up to 20 days and the main symptoms were fever and sore throat (41).

Knowledge of the anatomical relationships between the spaces of the neck is important for therapeutic management, because the fascia limiting these spaces represent important anatomical barriers to the spread of infection, but also serves to direct infection once its natural resistance is overcome (42).

Other indicators of health care use, such as medications used before and frequency, were not possible to obtain because most patients received treatment for their acute episodes in remote locations, either by their primary care physicians or by their local ENT specialist. However, this may probably be caused by the history of antibiotic abuse and antibiotic resistance explained by the indiscriminate use of antibiotics, especially in colds and other viral infections, which are more prevalent in children than in adults. Prior antibiotic use is correlated with greater recovery of resistant organisms and increased incidence of lactamase-producing bacteria (43).

Adults have infections of the cervical

spaces with multiple interest, this being due to the increased incidence of comorbidities in adults compared to children. Patients with comorbidities tend to have weaker defenses against infections and thus result in higher rates of severe infections that also lead to death.

The microbiology of deep cervical suppurations is characterized by being generally polymicrobial infections, including aerobic and anaerobic, gram positive in particular. Among the pathogens commonly found were: *Streptococcus viridans*, *Streptococcus milleri*, *Prevotella spp.*, *Pepto streptococcus spp.* and *Klebsiella pneumoniae*, the latter being more common in diabetic patients (26). Sennes found *Streptococcus viridans* in 41.5% of cases, *Staphylococcus aureus* in 20.7% of them and 3.8% with *Haemophilus influenzae* (44).

Many studies have shown the association of diabetes mellitus with deep suppurations (9, 11). In patients with diabetes, hyperglycemia can affect several humoral defense mechanisms of the host, such as the modification of neutrophil values, function: adhesion, chemotaxis and phagocytosis, leading to increased predisposition to infection and complications (21). Huang *et al*. found high rates of *Klebsiella pneumoniae* infection in diabetic patients (35).

The management of deep neck infections has evolved significantly over the years, due to ongoing input from by clinical studies, retrospective analyses, and expert consensus.

The literature consistently prioritizes airway management due to the potential for rapid deterioration in patients with DNI. Early recognition of airway compromise and proactive measures, such as intubation or tracheostomy, are critical to prevent life-threatening complications (17).

There is strong consensus on starting broad-spectrum antibiotics immediately upon diagnosis to cover the common pathogens (e.g., *Streptococcus*, *Staphylococcus*, and anaerobes). Empiric regimens often include combinations like ampicillin-sulbactam or clindamycin with a third-generation cephalosporin (25).

Adjusting antibiotic therapy based on culture results and sensitivity patterns is emphasized to avoid resistance and ensure efficacy. This tailored approach is supported by numerous studies highlighting improved outcomes with targeted therapy.

CONCLUSIONS

The management of DNI requires a nuanced approach that balances prompt, aggressive treatment with careful consideration of individual patient factors. Advances in diagnostic imaging and minimally invasive techniques offer new avenues for improving patient outcomes while reducing the risks associated with traditional surgical interventions. Ongoing research and clinical trials are essential to refine these approaches further and address the challenges posed by antibiotic resistance and evolving pathogen profiles. The key to successful management lies in early and accurate diagnosis, appropriate use of antibiotics, timely surgical intervention when necessary, and a multidisciplinary approach to care. This ensures effective control of the infection and minimizes the risk of complications, ultimately improving patient outcomes.

CONFLICT OF INTEREST AND FUNDING

The authors declare no conflicts of interest. This research received no external funding.

PREDICTIVE FACTORS FOR HEALTH-RELATED QUALITY OF LIFE IN TYPE 2 DIABETES PATIENTS (Abstract) **Aims:** Diabetes-related characteristics and associated chronic conditions are said to influence the health-related quality of life (QoL) of patients with type 2 diabetes mellitus (T2DM). This study assessed the relationships between QoL, demographic, and disease-related variables in T2DM patients without established atherosclerotic disease. **Materials and methods**: This post hoc analysis included outpatient data from a cross-sectional study. Descriptive and inferential statistics were used to examine patient characteristics in relation to QoL scores and identify predictive factors for physical and mental health perceptions. QoL was evaluated with the 36-item Short Form Health Survey (SF-36) questionnaire. **Results**: The 138 T2DM patients enrolled were 49.3% men, 57.86 ± 8.82 years old, with T2DM for 1 to 21 years, without optimal glycemic control under oral glucose-lowering drugs (median HbA_{1c}7.8%). Mean physical and mental component summary scores (PCS, MCS) were 50.44 ± 16.22 and 47.78 ± 12.10, respectively. The lowest SF-36 scores were reported for physical functioning and vitality, and the highest for bodily pain. Women had significantly lower PCS scores compared to men (46.85 *vs.* 54.03, $p = 0.01$). The diastolic index E/e', CHA_2DS_2-VASc score and diabetes duration predicted lower PCS ($p \leq 0.01$), while the impact of age, glycemic control, neuropathy, diastolic dysfunction, and comorbidities on QoL was non-significant. The diastolic index E/e', CHA_2DS_2-VASc score and diabetes duration predicted lower PCS ($p \leq 0.01$). **Conclusions:** These results provide a nuanced view of what is clearly a complex set of relationships. Further longitudinal studies are necessary to ascertain the effects of these variables on the quality of life of T2DM patients. **Keywords:** QUALITY OF LIFE, SF-36V2, TYPE 2 DIABETES.

Health-related quality of life (HRQoL) is a multidimensional concept first introduced half a century ago that provides an accurate, comprehensive, and concise view of patients' perceived impact of chronic disease (with or without comorbidities) on their

lives. It considers physical, mental, cognitive, and psychosocial aspects. Diabetes mellitus has been independently associated with lower HRQoL scores, similar to pulmonary, cardiovascular, and oncologic conditions. The quality of life of patients with diabetes is a psychosocial concern with implications for their long-term adherence to treatment (1, 2, 3). Current recommendations highlight diabetes-related psychosocial screening and care protocols as an important component that should be integrated into annual routine diabetes management practices to prevent or delay complications and optimize quality of life (4, 5).

Self-reported data on general health, physical status, social functionality, emotional well-being, and self-care capacity provide a meaningful context for achieving the clinical and biological goals of medical, nutritional and pharmacologic interventions. HRQoL has been studied as a primary or secondary outcome in both observational and interventional studies, often using the Short Form 36 (SF-36), a standardized, freely available, easy-to-administer questionnaire (6, 7). SF-36 assesses perceived health status across multiple scales - general, physical, mental, and social functioning. Although SF-36 was not developed specifically for people with diabetes, it helps explore relevant issues in the lives of these patients (8).

This study aimed to analyze the relationships between QoL data surveyed with SF-36v2 and clinical-biological parameters in type 2 diabetes (T2DM) patients with incidental echocardiographic findings of diastolic dysfunction (DD), but without established atherosclerotic disease.

MATERIALS AND METHODS

This is a post hoc analysis of outpatient data collected from T2DM patients presenting at the Clinical Centre of Diabetes, Nutrition, and Metabolic Diseases Iasi between June 2016 and February 2018. It is part of a larger prospective observational study approved by the Ethics Committees of "Grigore T. Popa" University of Medicine and Pharmacy Iași and of "Sf. Spiridon" Emergency Clinical Hospital Iași.

The study enrolled 138 consenting T2DM patients treated with metformin and/or sulfonylurea or acarbose, and who were eligible for additional incretin-based medication due to inadequate glycemic control (HbA_{1c} > 7%). The exclusion criteria were: HbA_{1c} < 7%, type 1 or secondary pancreatic diabetes, elevated triglycerides >400 mg/dL, uncontrolled blood pressure (>140/90 mmHg), cardiovascular disease (atherosclerotic manifestations, valvular heart disease, moderate/severe mitral annular calcification, dysrhythmias, cardiac pacemakers), history of inflammatory acute/chronic conditions (pancreatitis, liver failure, gastrointestinal and kidney diseases, malignancies), psychiatric disorders, pregnancy or intention to become pregnant, and smoking or recent history of smoking (< 1-year withdrawal). The enrollment process was described in more detail in Grigorescu *et al*, 2021, 2023 (9, 10).

The patients underwent physical examination, blood and urine sample tests (lipids, glycated hemoglobin HbA_{1c}, glycemia, insulin, C-peptide, high sensitivity C-reactive protein, interleukin (IL)-6, Tumour Necrosis Factor (TNF)-alpha, uric acid, etc.), and resting electrocardiography (11). Values of the ratio between mitral E wave velocity and mitral A wave velocity (E/A), mitral annular velocity with tissue Doppler imaging (e'), left ventricular ejection fraction (LVEF), fractional shortening (FS), E-

wave deceleration time (EDT), isovolumic relaxation time (IVRT), interventricular septum (IVS), left ventricular posterior wall (LVPW), left atrium volume (LAV) were measured by transthoracic echocardiography. The estimated glomerular filtration rate (eGFR) was computed using the CKD-EPI creatinine equation. The methods used for measuring HbA_{1c} and immunological parameters were DCCT-aligned ion-exchange high-performance liquid chromatography (Bio-Rad D-10™) and chemiluminescence (IMMULITE 1000). The thromboembolic risk score CHA_2DS_2-VASc was calculated based on age > 75 years, female sex, the presence of diabetes, congestive heart failure, hypertension, vascular disease, and past stroke events (12).

The patients were also asked to complete the Romanian version of the SF-36v2 questionnaire, consisting of 36 items grouped into 8 domains: Physical Functioning Scale (10 items), Physical Impairment Problems Scale (4 items), Social Functioning Scale (2 items), Physical Pain Scale (2 items), Mental Health Scale (5 items), Problems Caused by Emotional States Scale (3 items), Vitality Scale (4 items). All responses were re-coded to a linear 0-100 scale, with higher scores indicating better HRQoL. The two summary scores - the *physical component summary* (PCS) and the *mental component summary* (MCS) - were calculated according to the user's manual: the PCS was comprised of the scales PF, RP, BP, and GH, while MCS was computed from the remaining RE, SF, MH, and VT scales (6).

The statistical analysis was performed using IBM SPSS Statistics for Windows (version 20, SPSS Inc, Chicago, IL, USA). P-values < 0.05 were considered statistically significant. Continuous variables were assessed for conformity to normal distribution using the Kolmogorov-Smirnov test. Parametric and non-parametric tests (ANOVA, Kruskal-Wallis, Mann-Whitney U) were applied to compare mean/median questionnaire scores or mean ranks between specific groups (i.e., stratified by gender, presence of neuropathy). Receiver-operating characteristic (ROC) curves and areas under the curves (AUCs) were also considered (13).

RESULTS

Data collected from 138 patients aged 57.86±8.82, of whom 49.3% were men, are summarized in tables I and II. The patients had a diabetes history of 1 to 21 years (median value 5) and HbA_{1c} levels >7% on enrollment. The SF-36 scores averaged 50.44 ± 16.22 for self-reported physical health (PCS) and 47.78 ± 12.10 for the mental component (MCS). More details are shown in tables II and IV.

PCS had a weak association with eGFR ($r = 0.217$, $p = 0.011$), CHA_2DS_2-VASc ($r = -0.219$, $p = 0.01$), and E/e' ($r = -0.213$, $p = 0.013$), while MCS was associated with E/e' ($r = -0.202$, $p = 0.019$) and TNF-alpha ($r = -0.169$, $p = 0.048$) values. The following significant correlations were also noted between SF-36 components and patient characteristics:

- General health (GH) correlated with weight ($r = -0.169$, $p = 0.048$), abdominal circumference (WC, $r = -0.186$, $p = 0.029$), and LDL-cholesterol ($r = 0.194$, $p = 0.023$);
- Vitality (VT) correlated with left atrium length ($r = -0.185$, $p = 0.043$);
- Bodily pain (BP) correlated with CHA_2DS_2-VASc ($r = -0.250$, $p = 0.003$), HOMA-IR ($r = -0.190$, $p = 0.025$), index C-peptide ($r = 0.169$, $p = 0.047$), E/e' ($r = -$

0.173, p = 0.044), E/A (r = 0.170, p = 0.047), and EDT (r = 0.204, p = 0.017);

- Physical functioning (PF) correlated with CHA_2DS_2-VASc (r = -0.194, p = 0.022), C peptide (r = 0.184, p = 0.031), and HOMA-IR (r = 0.169, p = 0.048);

- Role physical (RP) correlated with age (r = -0.174, p = 0.041), CHA_2DS_2-VASc (r = -0.201, p = 0.018), and TNF-alpha (r = -0.208, p = 0.014).

Subgroup analyses based on age, sex, DD, degree of inadequate glycemic control, neuropathy, and other comorbidities (hypertension, dyslipidemia, obesity, metabolic dysfunction-associated fatty liver disease) revealed significant SF-36 score differences only for self-assessed physical health between men and women (54.03 vs. 46.85, p = 0.01) (table III). The presence of comorbidities did not seem to affect the PCS and MCS scores (16.7% of patients had three comorbidities, 42% had two, and 32.6% had just one). Patients with mitral annular calcifications and/or aortic atheromatosis had higher MCS scores (50.43 ± 12.06 vs 45.49 ± 11.74, p = 0.016), similar to patients with dyslipidemia.

Further analyses based on the qualitative variables revealed significant differences for the following scales:

- patients with obesity had significantly lower scores (51.63 ± 17.89 vs 44.90 ± 16.88, p = 0.032) for **general health** compared to those with BMI < 30 kg/m^2;

- men reported higher scores for **bodily pain** compared to women (mean ranks 82.49 vs 56.89, p<0.01), and patients with neuropathy had lower scores for this scale (62.30 vs 75.30, p = 0.05);

- **social functioning** scores were lower in patients with ≥ 3 comorbidities (p = 0.041);

- **emotional role** scores were lower in patients with ≥ 4 criteria for metabolic syndrome (41.38 *vs.* 78.82, p = 0.05), which described almost all patients.

GH, general health; BP, bodily pain; MH, mental health; PF, physical functioning; RE, role emotional; RP, role-physical; VT, vitality; SF, social functioning; PCS, physical component summary; MCS, mental component summary; NS statistically non-significant: p > 0.05, r: coefficients of correlations with PCS and MCS.

ROC curves predictive of lower PCS were found for E/e' (AUC = 0.643, CI 0.549-0.736, p = 0.005), CHA_2DS_2-VASc (AUC = 0.623, CI 0.530-0.716, p = 0.013), and diabetes duration (AUC = 0.613, CI 0.549-0.736, p = 0.005), as illustrated in first figure.

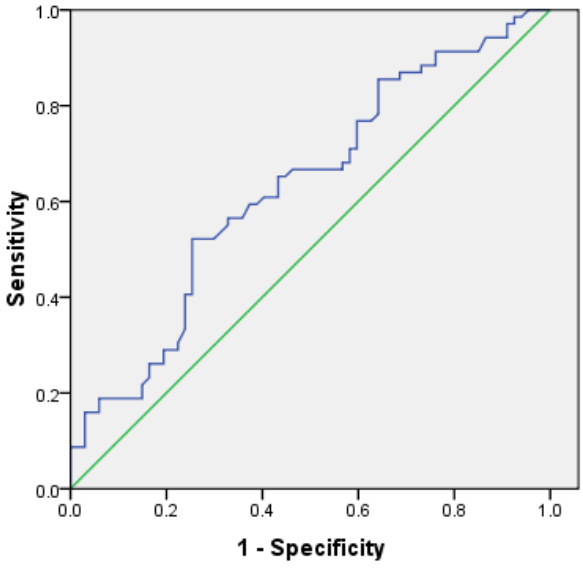

Fig. 1. Receiver-operating characteristics (ROC) curve for E/e'

DISCUSSION

There is growing interest in understanding and addressing the factors associated with a decline in health-related quality of life for people with type 2 diabetes as a way to improve healthcare services and patient adherence. This post hoc analysis of 138 T2DM Romanian patients without overt manifestations of atherosclerotic disease focused on the associations between patient-reported outcomes and characteristics with proported effects on QoL (metabolic profile, pre-existing chronic conditions).

QoL was assessed using the PCS and MCS scores of the SF-36v2 questionnaire, similar to other published and ongoing observational and interventional research from Europe and elsewhere (14, 15, 16). A minimum SF-36 score change of 3-5 points has been proposed as clinically relevant, with due caution when interpreting it as a significant improvement or decline. Furthermore, comparisons across studies should be made with circumspection, acknowledging the substantial heterogeneity of the studied populations in terms of their general, metabolic, and pathology-related characteristics (17, 18, 19).

In our study, the lowest SF-36 scores were reported for physical functioning, followed by vitality, and the highest were for bodily pain. Compared to previous research on age-standardized Romanian general population, our patients' PCS and MCS scores were substantially lower: 74.52 ± 19.44 vs. 50.44 ± 16.22 and 71.70 ± 19.02 vs 47.78 ± 12.10, respectively (20). At the same time, the mean PCS and MCS values were within the range of scores reported for patients with diabetes from other geographical regions/countries: Greece (39.96 and 38.24), Spain (44.9 and 51.2), Netherlands (49.4 and 53.9), India (52 and 46), Ethiopia (40.15 and 48.11), and United States (52 and 46) (21, 22, 19, 23, 24, 25). Moreover, the mean values of our patients' PCS and MCS scores were comparable to those reported in other clinical research investigating the effects of new drugs or weight loss programs (26, 27, 28, 16). For example, in an interventional clinical trial on 563 uncontrolled T2DM patients of similar mean age (55 years), slightly higher HbA_{1c} (8.32%), and higher BMI (37.1 kg/m^2), an intensive weight loss program yielded no significant differences in SF-36 scores assessed after 12 months, compared to a control group: PCS 45.7 vs 45.2, and MCS 51.5 vs 51.6 (16).

While some researchers have demonstrated associations between glycemic control and HRQoL domains, in other studies and our analysis, HbA_{1c} was not associated with PCS and MCS (29). In a multivariate analysis of 5-year data from 1,876 patients with T2DM from Denmark, the Netherlands, and the UK, no significant associations were identified between HbA_{1c} and SF-36 scores after adjustment for age, sex, BMI, type of antihyperglycemic drugs, and education status. Even so, 60% of the patients with HbA_{1c} below 7% and who were treated with oral medication had higher SF-36 scores (PCS 46.2 and MCS 54.6) (30). In another study where 1,352 patients with T2DM filled out the SF-36 questionnaire, a multivariate analysis adjusting for disease duration and other risk factors found significantly higher PCS and MCS scores in patients with an HbA_{1c} below 6.9% versus above 8.6% (31). These differing results across studies suggest that we have yet to learn about the complexities of the proport-

ed relationships.

At the same time, systematic reviews and meta-analyses confirm that patients with a longer duration of diabetes, chronic complications and hypertension have lower QoL scores. In our data, patients' quality of life decreased as the duration of the disease increased, which is consistent with the results of other studies (14). However, the difference was significant only for MCS.

Comorbidities were highly prevalent in our study, especially hypertension (67.4%), dyslipidemia (71.74%), and MAFLD (75.46%) only twelve patients had none. Almost all patients had abdominal obesity and metabolic syndrome, of which 60.9% met at least 4 criteria. In addition, 83 patients had diastolic dysfunction diagnosed according to the 2016 guideline, of whom 71 with grade 1 severity (and all the patients had normal systolic function). By comparison, the prevalence of these common chronic conditions in other studies varied from 27.71% to 78.2% for hypertension, from 43.5% to 98.3% for dyslipidemia, and was only 32.8% for the metabolic syndrome (32, 24, 33, 34). Our data set was, therefore, suitable for exploring the relationship between comorbidities and QoL.

Available research into the impact of comorbidities on the quality of life in type 2 diabetes patients has been reviewed recently in a meta-analysis, with the key finding that each additional chronic condition decreased the PCS score by approximately 3% (36). Nonetheless, in our study, the number of comorbidities did not appear to undermine the health-related quality of life, nor did the presence of subclinical diastolic dysfunction, which is consistent with other studies that evaluated such relationships (19, 37). This raises interesting questions for further research, e.g. could a satisfying relationship with one's physician, good adherence to medical treatment, or some other aspects of healthcare give patients a certain level of psychological comfort and reassurance that counterbalances the otherwise negative impact of the disease severity and complexity?

In addition, DD did not correlate with QoL either, similar to the findings of Edelman *et al.*, 2011 (38*).* However, we noted that the diastolic index E/e' was a significant predictor for lower scores attributed to physical health. E/e' was also significantly higher in patients with PCS and MCS scores below median values. This could be investigated further, considering the well-known role of echocardiographic parameters in one's objective vitality, as well as recent research supporting the inclusion of the self-reported SF-36 vitality item in the cardiovascular risk stratification algorithms for T2DM patients (39).

In our previous research, DD was predicted by the CHA2DS2-VASc score (40). Typically, CHA2DS2-VASc serves as a decision-making tool when establishing the need for anticoagulant therapy in patients with atrial fibrillation. Recently, more potential applications have been explored, such as for the prediction of rehospitalization and all-cause mortality or in the risk assessment for cardiac and cerebrovascular events even in patients without atrial fibrillation (41, 42, 43). In this study, CHA2DS2-VASc was predictive of a poorer quality of life in terms of perceived physical health. From a practical perspective, this score is based on readily available data and is easy for diabetes specialists to calculate during routine check-ups, so it is worth knowing and exploiting its full predictive potential.

The relatively small number of participants is a limit of this study, and further multivariate analysis was not appropriate because of insufficient demographic data (marital, educational or employment status), psychological data (stress or anxiety levels), or health literacy levels. The nature of this post hoc analysis could not support assertions of causality explaining the observed associations. Moreover, all patients had HbA_{1c} levels above 7% and no severe complications, so comparisons with data from patients with adequate glycemic control were not possible in our study.

We recognize the complex relationship between HRQoL, diabetes-specific, and other factors. The use of a validated tool to assess patient-reported outcomes, the nuanced analysis, and the identification of predictors for a lower quality of life are the main strengths of this study. The results can contribute to international data collection efforts and allow the experiences of Romanian patients to be included in forthcoming meta-analyses.

CONCLUSIONS

In this study of T2DM patients without established atherosclerotic disease, self-reported quality of life was mostly independent of diabetes-related factors such as glycemic control, chronic complications, and comorbidities. Conversely, diabetes duration, the diastolic index E/e', and CHA_2DS_2-VASc score, were associated with lower physical health perception. This and other forthcoming studies can inform the design of prospective and interventional research, as well as educational programs targeting better quality of life for T2DM patients as a primary or secondary endpoint.

RETROSPECTIVE STUDY ON THYROID FUNCTION MODIFICATIONS IN PATIENTS DIAGNOSED WITH POLYCYSTIC OVARY SYNDROME (Abstract): Polycystic ovary syndrome (PCOS) is a complex endocrine condition, and its association with thyroid dysfunction is variably reported in the literature. The **aim** of the study was to retrospectively evaluate the degree of association between PCOS and thyroid impairment in a cohort of 269 patients. **Materials and methods:** The study had a retrospective observational design. The data were analyzed descriptively and using a multivariate logistic regression model to analyze the association between thyroid status and the type of thyroid disorder with each PCOS phenotype individually. The results were reported as relative risk ratios (RRR) and 95% confidence intervals (CI). **Results:** The presence of phenotype A in the context of advanced age increased the risk of developing hyperthyroidism by 9% (RRR: 1.06, 95% CI: 1.01-1.12, p=0.019), while in the context of a normal or low BMI, it decreased the risk of developing hyperthyroidism by 93% (RRR: 0.07, 95% CI: 0.08-0.68, p=0.021). Phenotype B in the context of a normal or low BMI increased the risk of developing hyperthyroidism by over 15 times (RRR: 15.86, 95% CI: 1.23-30.3, p=0.03). **Conclusions:** Early identification of thyroid abnormalities in patients with PCOS is warranted and requires an individualized therapeutic approach. **Keywords:** POLYCYSTIC OVARY SYNDROME; THYROID DISORDERS; HYPOTHYROIDISM; HYPERTHYROIDISM.

INTRODUCTION

Thyroid disorders are diagnosed in approximately 14% of adult women, particularly those of reproductive age (1). Female sex is one of the most significant clinical risk factors associated with the onset of thyroid dysfunction, with this risk factor increasing the likelihood of these disorders by 3-5 times in the female population compared to the male population (2, 3).

Additionally, certain ethnic groups or those with specific clinical characteristics are more prone to thyroid dysfunction, with patients from the Asian region or those who are overweight presenting the highest risk (4, 5). On the other hand, there is a documented dual relationship in the literature between thyroid disorders and polycystic ovary syndrome (PCOS), with significant metabolic and reproductive effects in the context of this association (6).

Subclinical hypothyroidism is linked to

the presence of the polycystic ovarian syndrome (PCOS), with these patients at increased risk for dyslipidemia or insulin resistance (7). Patients diagnosed with autoimmune thyroid disorders, such as Graves' disease or Hashimoto's thyroiditis, also present an increased risk of developing infertility and/or premature ovarian insufficiency (8).

The effects of thyroid dysfunction on the female reproductive system are complex and can manifest both directly and indirectly (9). Thyroid hormones control the release of kisspeptin and GnRH at the hypothalamic-pituitary level by directly influencing the secretion of these hormones and also through their response to metabolic signals such as prolactin and leptin (10-12).

Furthermore, thyroid hormones influence the availability of sex hormones by modifying binding proteins (13). An euthyroid status promotes the proper functioning and growth of the female reproductive system and regulates the development of the placenta and fetus during pregnancy (14, 15).

A thorough examination of the complex relationship between the thyroid and the female reproductive system is necessary to fully understand the factors that influence the clinical phenotype of the association between PCOS and thyroid dysfunction (16, 17).

To date, data from the literature support the association of thyroid dysfunctions with a range of reproductive abnormalities such as premature ovarian insufficiency, PCOS, infertility, irregular menstrual cycles, abnormal bleeding, and adverse obstetric outcomes.

However, the direct impact of thyroid hormones on reproduction is complicated by the frequent connection between autoimmune diseases and dysfunctions of both the thyroid system and the reproductive system.

Fluctuations in thyroid hormone levels among patients with PCOS continue to be a subject of debate. A study conducted in Denmark demonstrated that patients diagnosed with PCOS have a two-fold higher risk of developing hyperthyroidism compared to age-matched patients without PCOS (18).

Several studies have shown a higher prevalence of hypothyroidism in patients with PCOS compared to the prevalence of hyperthyroidism (19, 20). However, another study indicated that there is no significant difference in the incidence of thyroid diseases between patients with or without this condition (21).

In this study, we aimed to retrospectively evaluate the degree of association between polycystic ovary syndrome and thyroid hormonal disorders in a cohort of patients who presented for evaluation at a referral center in the Moldova region.

MATERIALS AND METHODS

In this retrospective cohort study, we analyzed all patients diagnosed with PCOS who sought care at the endocrinology clinic of “Sf. Spiridon” County Clinical Emergency Hospital in Iași, during the period from January 1st, 2017, to December 31st, 2022. We confirm that all the procedures were followed in accordance with the relevant guidelines of the Helsinki declaration. Ethical approval for conducting this study was obtained from the Research Ethics Committee of the “Grigore T. Popa” University of Medicine and Pharmacy in Iași (No. 132/14.12.2021).

The database query was made based on discharge diagnoses from the department,

using the ICD code (International Classification of Diseases and Related Health Problems, version 2010) corresponding to PCOS - E28.2 Polycystic Ovary Syndrome. All data extracted from the query were anonymized and statistically processed.

In addition to the diagnosis of PCOS, we used the following inclusion criteria for this cohort study: age of patients between 18 and 80 years, complete medical records, patients with or without thyroid dysfunction, patients with or without thyroid-stimulating medication, definitive diagnosis of PCOS according to Rotterdam criteria (22, 23).

Patients were excluded from this study if they met any of the following criteria: pregnant patients, underaged or patients over 80 years of age, incomplete diagnosis or monitoring, those who did not sign consent for processing personal data upon admission, patients with severe comorbidities (advanced malignant neoplasms, HIV/AIDS infection, severe neurological, cardiovascular, and pulmonary conditions).

Medical data from 269 patients who met the inclusion criteria were subsequently analyzed. We focused on the following types of data: age, body mass index (BMI), living environment, PCOS phenotype, presence of obesity, dyslipidemia, diabetes, chronic arterial hypertension (HBP), hirsutism, or infertility, thyroid status: euthyroidism, hypothyroidism, or hyperthyroidism, type of thyroid impairment: autoimmune thyroiditis, non-toxic multinodular goiter, thyrotoxicosis, Graves' disease.

Patients with PCOS were segregated according to the phenotype of the disease based on the Rotterdam criteria into (22, 23):

- phenotype A, characterized by the association between clinical or biochemical hyperandrogenism, ovulatory dysfunction, and typical PCOS morphology (group 1, n= patients);
- phenotype B, characterized by the association of clinical or biochemical hyperandrogenism with ovulatory dysfunction (group 2, n= patients);
- phenotype C, characterized by the association of clinical or biochemical hyperandrogenism with typical PCOS morphology on ultrasound (group 3, n= patients);
- phenotype D, characterized by the combination of ovulatory dysfunction and ultrasound morphology of PCOS (group 4, n= patients);

The first stage of our statistical analysis was the description of the data used, for which we employed histogram-type graphs to assess the distribution of various characteristic types among the analyzed groups. Nominal characteristics were subsequently compared using chi-square or Fisher's exact tests depending on the type of distribution. Numerical variables were also compared among the main study groups using ANOVA and the Bonferroni post-hoc test. Violin plots and boxplots were used to illustrate the differences between the serum parameters across the evaluated groups and subgroups. We also analyzed the degree of correlation between serum hormone levels and thyroid impairment.

Subsequently, we created a multivariate logistic regression model to analyze the association between thyroid status and the type of thyroid disorder with each PCOS phenotype separately. The model was adjusted for the age and body mass index of the patients, and the results were reported as relative risk ratios (RRR) and 95% confidence intervals (CI). Statistical analyses were conducted using *STATA SE software*

(version 17, Stata Corp LLC, College Station, TX, USA). A nominal p-value less than 0.05 was considered statistically significant.

RESULTS

Table I presents a comparison of the clinical characteristics among the main study groups. We found that the studied groups were homogeneous in terms of patient age and living environment. On the other hand, we noted that patients diagnosed with phenotype A of the disease exhibited significantly higher rates of obesity (A: 45.53% vs. B: 14.44% vs. C: 14.71% vs. D: 13.64%, p<0.001), dyslipidemia (A: 30.89% vs. B: 12.22% vs. C: 20.59% vs. D: 13.64%, p=0.009), and diabetes mellitus (A: 14.63% vs. B: 1.11% vs. C: 2.94% vs. D: 0%) compared to the other phenotypes.

TABLE I.
Clinical characteristics of the study groups

	Group 1 (Phenotype A, 123 patients)	Group 2 (Phenotype B, 90 patients)	Group 3 (Phenotype C, 34 patients)	Group 4 (Phenotype D, 22 patients)	p-value
Age years (median, IQR)	30 (18-71)	27 (18-74)	24 (18-70)	26 (19-58)	0.86

Infertility (%)	3.25%	1.11%	0%	0%	0.45

IQR- interquartile range

Figure 2 shows the distribution of types of thyroid impairment according to the disease phenotype. The highest rates of hypothyroidism were found in patients with phenotype D (18.18%) and A (15.45%) compared to those with phenotype B (7.77%) and C (2.94%).

Additionally, the highest rates of hyperthyroidism were found in patients diagnosed with phenotype A (8.13%) and C (5.88%), followed by phenotypes D (4.54%) and B (3.33%) in terms of hyperthyroidism prevalence.

It is noteworthy that there was a relatively high prevalence of euthyroidism for all analyzed phenotypes: phenotype C (91.18%), B (88.89%), D (77.27%), and A (76.42%). The overall distribution of hypothyroidism in the studied population was 11.52%, hyperthyroidism was 5.94%, and euthyroidism was 82.53%.

As shown in figure 3, autoimmune thyroiditis had a high prevalence across all evaluated groups. Thus, the highest prevalence was found in phenotype D (81.82%) and C (67.65%), while the prevalence of hypothyroidism was relatively similar for phenotypes A and B (52.03% and 52.22%).

Non-toxic multinodular goiter was relatively common in the studied population, with rates of this condition being 24.39% for phenotype A, 18.89% for phenotype B, 17.65% for phenotype C, and 13.64% for phenotype D.

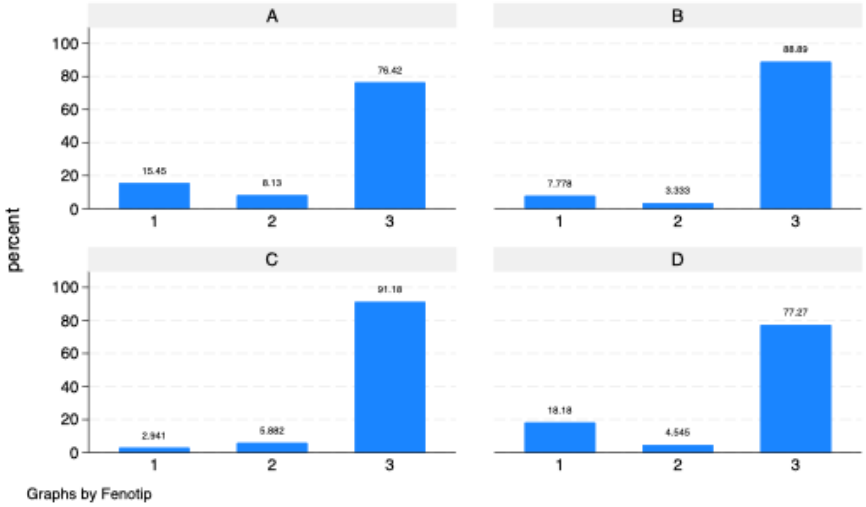

Fig. 1. Distribution of the type of thyroid impairment according to the studied phenotype. Legend: 1 - hypothyroidism, 2 - hyperthyroidism, 3 - euthyroidism.

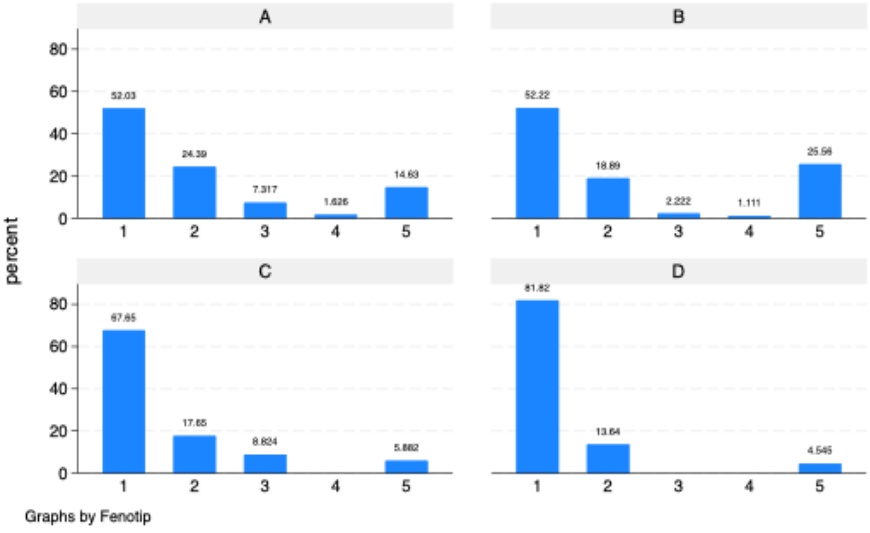

Fig. 2. Distribution of thyroid disorders according to the studied phenotype. Legend: 1 - autoimmune thyroiditis, 2 - non-toxic multinodular goiter, 3 - thyrotoxicosis, 4 - Graves' disease, 5 - without disorders.

Thyrotoxicosis was seen in 8.825% of patients with phenotype C, 7.31% of patients with phenotype A, and 2.22% of patients with phenotype B. Lastly, Graves' disease was observed in 1.62% of patients with phenotype A, 1.11% of patients with phenotype B, and 0% of patients with phenotypes C or D. The rate of patients without thyroid disorders in the examined groups was 25.56% for phenotype B, 14.63% for patients with phenotype A, 5.88% for patients with phenotype C, and 4.54% for patients with phenotype D.

The overall prevalence of thyrotoxicosis in the examined cohort was 56.51%, nontoxic multinodular goiter was 20.82%, thyrotoxicosis was 5.20%, and Graves' disease was 1.11%. A total of 16.36% of patients showed no evidence of thyroid impairment.

We subsequently evaluated a multinomial logistic regression model that aimed to identify the association between thyroid status and each PCOS phenotype individually. The model was adjusted for the age and body mass index of the patients (tab. II).

TABLE II.

The results of the adjusted multinomial logistic regression model that evaluated the association between PCOS phenotypes and thyroid status.

Adjustment	Thyroid Status	Phenotype A	P	Phenotype B	P	Phenotype C	p	Phenotype D	P
		RRR and 95%CI		RRR and 95%CI		RRR and 95%CI		RRR and 95%CI	
Age	Hypo T	0.99 (0.95- 1.04)	0.98	0.99 (0.92-1.05)	0.77	0.95 (0.71-1.26)	0.72	0.98 (0.87- 1.10)	0.80
	Hyper T	1.06 (1.01- 1.12)	0.019	0.99 (0.90-1.09)	0.98	1.08 (0.98-1.20)	0.10	0.79 (0.42-1.47)	0.46
BMI	Hypo T	0.42 (0.14- 1.22)	0.11	3.32 (0.53- 20.45)	0.19	1.35 (0.32-1.90)	0.99	2.89 (0.15- 55.08)	0.48
	Hyper T	0.07 (0.08- 0.68)	0.021	15.86 (1.23- 30.3)	0.03	4.25 (0.16-10.9)	0.38	5.31 (0.48- 15.3)	0.99

RRR- relative risk ratio, CI- confidence interval, BMI- body mass index, T- thyroidism.

Our results showed that the presence of phenotype A in the context of advanced age (over 35 years) increased the risk of developing hyperthyroidism by 9% (RRR: 1.06, 95% CI: 1.01-1.12, p=0.019).

Additionally, the presence of phenotype A in the context of a normal or low BMI (less than 25 kg/m²) decreased the risk of developing hyperthyroidism by 93% (RRR: 0.07, 95% CI: 0.08-0.68, p=0.021).

On the other hand, phenotype B in the context of a normal or low BMI (less than 25 kg/m²) increased the risk of developing hyperthyroidism by over 15 times (RRR: 15.86, 95% CI: 1.23-30.3, p=0.03).

Finally, the presence of any phenotype did not significantly increase the risk of developing hypothyroidism when adjusted for age or body mass index. For example, the decrease in the risk of hypothyroidism ranged between 1 and 5 percent in the context of a young patient age (under 35 years): phenotype A (RRR: 0.99, 95% CI: 0.95-1.04, p=0.98), phenotype B (RRR:

0.99, 95% CI: 0.92-1.05, p=0.77), phenotype C (RRR: 0.95, 95% CI: 0.71-1.26, p=0.72), or phenotype D (RRR: 0.98, 95% CI: 0.87-1.10, p=0.80).

Subsequently, we evaluated a multinomial logistic regression model that aimed to identify the association between thyroid impairment and each PCOS phenotype individually. The model was adjusted for the age and body mass index (BMI) of the patients, and the results are presented in third table.

TABLE III.

The results of the adjusted multinomial logistic regression model that evaluated the association between PCOS phenotypes and thyroid impairment.

Adjustment	Thyroid Status	Phenotype A	P	Phenotype B	P	Phenotype C	p	Phenotype D	P
		RRR and 95%CI		RRR and 95%CI		RRR and 95%CI		RRR and 95%CI	
Age	Auto immune Thyroiditis	1.02 (0.97- 1.08)	0.33	1.00 (0.96- 1.06)	0.69	1.34 (0.88-2.06)	0.16	1.06 (0.76- 1.49)	0.71
	Nodular Goiter	1.08 (1.02- 1.15)	0.006	1.05 (0.99- 1.11)	0.08	1.59 (1.01-2.50)	0.04	1.61 (0.73- 3.55)	0.23
BMI	Auto immune Thyroiditis	0.14 (0.04- 0.49)	0.002	2.8 (0.88- 6.41)	0.98	1.96 (0.42-3.98)	0.99	4.98 (0.76- 16.22)	0.99
	Nodular Goiter	0.29 (0 .07- 1.17)	0.08	5.22 (0.19- 25.48)	0.98	4.27 (0.35-11.8)	0.99	3.16 (0.55- 13.4)	0.99

RRR- relative risk ratio, CI- confidence interval, BMI- body mass index.

Our results indicated that phenotype A significantly increased the risk of developing non-toxic nodular goiter by 8% in the context of advanced age (RRR: 1.08, 95% CI: 1.02-1.15, p=0.006). Additionally, our model indicated a significant 59% increase in the risk of developing non-toxic nodular goiter in the context of advanced age and phenotype C (RRR: 1.59, 95% CI: 1.01-2.50, p=0.04).

Last but not least, the risk of developing autoimmune thyroiditis was significantly increased in the context of being diagnosed with phenotype A and having an increased body mass index (greater than 25 kg/m²) (RRR: 0.14, 95% CI: 0.04-0.49, p=0.002). On the other hand, our results did not indicate an increased risk of developing autoimmune thyroiditis when adjusted for patient age.

Thus, the risk of developing autoimmune thyroiditis in the context of having phenotype A was 2% (RRR: 1.02, 95% CI: 0.97-1.08, p=0.33), with phenotype B it was 0% (RRR: 1.00, 95% CI: 0.96-1.06, p=0.69), with phenotype C it was 34% (RRR: 1.34, 95% CI: 0.88-2.06, p=0.16), and with phenotype D it was 6% (RRR: 1.06, 95% CI: 0.76-1.49, p=0.71).

DISCUSSION

The global prevalence of polycystic ovary syndrome (PCOS) is estimated to be between 6% and 10% for unselected populations (24). The literature identifies a variety of risk factors that increase the likelihood of developing this condition as well as the risk of developing thyroid disorders (25, 26).

This retrospective study provided an ex-

tensive description of PCOS pathology in terms of clinical and paraclinical characteristics, as well as the associations of this pathology with thyroid dysfunction. As such, we demonstrated that the studied groups were homogeneous in terms of patient age and living environment. Additionally, we showed that patients diagnosed with phenotype A of the disease presented significantly higher rates of obesity (A: 45.53% vs. B: 14.44% vs. C: 14.71% vs. D: 13.64%, $p<0.001$), dyslipidemia (A: 30.89% vs. B: 12.22% vs. C: 20.59% vs. D: 13.64%, $p=0.009$), and diabetes mellitus (A: 14.63% vs. B: 1.11% vs. C: 2.94% vs. D: 0%) compared to the other phenotypes.

From this perspective, phenotype A appears to be associated with most of the metabolic dysfunctions present in the studied cohort. Our data agree with findings published in the literature.

The prevalence of PCOS phenotypes is variably reported in the literature. Thus, the prevalence of phenotype A has been reported to range from 44.1% to 64.5%, phenotype B from 7.9% to 32.6%, phenotype C from 2.9% to 28.8%, and phenotype D from 1% to 22.6% (352-355). In our study, the prevalence of phenotype A was 45.72%, phenotype B was 33.45%, phenotype C was 12.63%, and phenotype D was 8.17%, which overlaps with statistics from other countries.

Regarding the association of obesity with PCOS and its phenotypes, data from the literature confirm this link. For example, Moran and colleagues highlighted obesity rates of 48.2% for phenotype A, 22.7% for phenotype B, and 1.7% for phenotype C (27).

Bariatric surgery has proven to be a successful strategy for the treatment of morbid obesity; however, there are limited studies regarding its effect on PCOS in terms of improving clinical aspects, hormones, and comorbidities.

In a prospective observational study involving 1,013 patients diagnosed with PCOS who underwent bariatric surgery at a single center conducted by Bhandari and collaborators, the authors investigated the effectiveness of these procedures on the clinical and hormonal manifestations of PCOS (28).

In the studied cohort, 993 patients exhibited hirsutism before the surgical intervention, and 741 (74.6%; $p < 0.001$) had complete resolution of hirsutism by the end of the 6-month follow-up period. A total of 202 patients (20.3%) experienced moderate reduction in hirsutism at the 1-year follow-up, 5 patients had minimal reduction in hirsutism by the end of the 2-year follow-up, and 45 (4.5%) of patients reported no change in hirsutism at 4 and 5 years of follow-up (28).

Additionally, 93% of patients restored their normal menstrual cycle within 6 months after surgery, while the remaining 7% reported regular menstruation at 2 years postoperatively and continued to have a normal menstrual pattern throughout the entire follow-up period (28).

Similarly, associated comorbidities such as type II diabetes (79.7%), chronic hypertension (78.7%), dyslipidemia (93.2%), and obstructive sleep apnea (98.5%) resolved completely by the end of the follow-up period, highlighting the importance of performing these types of procedures in patients with PCOS and obesity (28).

Our results showed that the presence of phenotype A in the context of advanced age (over 35 years) increased the risk of developing hyperthyroidism by 9% (RRR: 1.06, 95% CI: 1.01-1.12, $p=0.019$). Additionally, the presence of phenotype A in the context of a normal or low BMI (less than 25

kg/m²) decreased the risk of developing hyperthyroidism by 93% (RRR: 0.07, 95% CI: 0.08-0.68, p=0.021).

On the other hand, phenotype B in the context of a normal or low BMI (less than 25 kg/m²) increased the risk of developing hyperthyroidism by over 15 times (RRR: 15.86, 95% CI: 1.23-30.3, p=0.03). Finally, the presence of any phenotype did not significantly increase the risk of developing hypothyroidism when adjusted for age or body mass index.

A study published in 2024 analyzed the association between PCOS and subclinical hypothyroidism and determined the potential impact of subclinical hypothyroidism on the clinical and metabolic characteristics of patients with PCOS (29). The results indicated a statistically significant difference between the two groups regarding obesity rates ($p = 0.014$) (29). Compared to the group of patients with PCOS, those with an association of both conditions exhibited significantly higher levels of TSH ($p < 0.001$), triglycerides ($p = 0.025$), and HOMA-IR ($p < 0.001$), while LH levels were significantly lower ($p = 0.048$).

However, the multivariate linear regression analysis revealed that TSH, triglycerides, LH, and HOMA-IR were not determinants for the occurrence of subclinical hypothyroidism in patients with PCOS (29).

Bonakdaran and colleagues evaluated the incidence of hypothyroidism in patients with PCOS and compared it in a group of healthy patients (30). Furthermore, the impact of hypothyroidism on metabolic parameters, particularly on insulin resistance, was examined in patients with PCOS.

The results of the study indicated that patients with PCOS had a higher incidence of hypothyroidism and a higher level of anti-peroxidase antibodies compared to the control group (30). HDL cholesterol was significantly higher in patients with PCOS and hypothyroidism than in those without hypothyroidism, although no significant differences were observed regarding other metabolic markers (30).

The results of this study should be analyzed considering a number of limitations: the small cohort of patients, the limited number of serum parameters included, and the lack of a control group without thyroid impairment.

On the other hand, our findings managed to describe aspects related to the prevalence of PCOS phenotypes in the evaluated patients, as well as their association with thyroid status and the most commonly encountered thyroid disorders.

CONCLUSIONS

The most frequently encountered PCOS phenotypes in the studied population were A and B. These phenotypes were significantly more associated with the development of thyroid disorders such as autoimmune thyroiditis, non-toxic multinodular goiter, or Graves' disease. Additionally, patients classified as phenotype A exhibited significantly higher rates of comorbidities such as dyslipidemia or chronic hypertension.

EVALUATION OF THE SUICIDAL MENTAL STATE OF PATIENTS HOSPITALIZED AT THE "SOCOLA" INSTITUTE OF PSYCHIATRY IAȘI (Abstract): Suicidal ideation and attempts are the most important predictive factors for death by suicide. Accordingly, in this study we performed a retrospective analysis of cases admitted to the "Socola" Psychiatric Institute in Iași regarding suicide attempts and/or suicidal ideation throughout 8 years of pre-pandemic period. **Materials and methods:** This retrospective study was based on data collected from the electronic archive of the "Socola" Institute of Psychiatry. To search for primary and secondary diagnoses, we used the following keywords: *suicide attempts, suicidal attempt, suicidal ideation* and *autolytic ruminations*. For statistical analysis, was used *Microsoft Excel* 2007. **Results:** The search yielded 257 cases, more than a quarter of which were young people, mostly women (63%). Of the patients whose brain activity was investigated (43%), 6% presented an altered EEG. In terms of occupation, 31% were professionally active people or students, the majority being retirees and those without occupation (56.4%). Of the 37% of patients whose religious denomination was recorded, 95% were Orthodox Christians. Also, 55% of all patients consumed alcohol, 69.6% suffered from family conflict, 6.6% were in a state of mourning, 18% performed the act for demonstrative purposes, and 42% were subjected to a psych stressful context. It was observed that depression, in various forms, represented around 35% of the total disease codes associated with suicidal attempts and ideation. Hypertension was the most frequent associated organic condition. It was also observed that people in the segment with primary or secondary education had the most suicidal attempts and ideation, and more than half of the patients presented an IQ bordering on normality. **Conclusions:** The analysis found that suicidal ideation and attempts continued to have a significant incidence in hospitalized cases, while depression, alcohol, and family conflicts were the most significant triggers. The study may represent an important landmark in relation to the Covid-19 pandemic and post-pandemic period. **Keywords:** SUICIDAL IDEATION, SUICIDAL ATTEMPTS, SUICIDE METHODS, DEPRESSION, RELIGION.

INTRODUCTION

Suicide is a global phenomenon but geographically unevenly distributed, with 77% of suicides occurring in low- and middle-income countries. Suicide occurs across the lifespan and is the fourth leading cause of death among young people aged 15-29 years worldwide (1). It is estimated that there were 700,000 suicide deaths worldwide in 2021 (2). In addition to deaths by suicide, increased attention should be paid to non-fatal suicide ideation and attempts (3) given

that overall lifetime prevalence rates are approximately 9.2% for suicidal ideation and 2.7% for attempts (Nock *et al*., 2008).

It is generally known that suicidal ideation and attempts are the most important predictors of death by suicide. In addition, suicide attempts are one of the main causes leading to disability, including premature death. Therefore, improved packages of preventive and therapeutic measures are needed in the medium and long term to better understand the phenomenon both globally and at the individual level, so that the insertion and judgment of each case are not absorbed by treatment models considered universally valid, but rather related to a social behavior pattern associated with an individual psychological and religious profile.

In addition, the prevention not only of suicide attempts, but also of suicidal ideation, perhaps also represents an act of moral responsibility of each member of the local community, based not only on the rationale of social responsibility towards a fellow human being in critical suffering, but also on that unconditional empathetic emotion, characteristic of human nature in general. Accordingly, Scientific investigations focused on the current scale of the phenomenon, its characteristics and proposals for improving the act of prevention must be carried out with increased frequency, being critical in relation to new social realities and the stressors associated with them in order to be able to both adjust traditional methods of therapeutic support as quickly as possible and to introduce new ones, if necessary, depending on the patient's requirements.

In this study, an analysis of cases admitted to the "Socola" Institute of Psychiatry in Iași regarding suicide attempts and/or suicidal ideation was carried out throughout 8 years of pre-pandemic period, in order to evaluate the dimension of the phenomenon, highlight one- or two-way relationships between the data collected based on the statistical interpretation of the results, and correlation with data from the specialized literature.

MATERIALS AND METHODS

This retrospective study was based on data collected from the electronic archive of the "Socola" Institute of Psychiatry. To search for primary and secondary diagnoses, we used the following keywords: *suicide attempts, suicidal attempt, suicidal ideation* and *autolytic ruminations.* For statistical analysis, was used *Microsoft Excel* 2007.

RESULTS

Following the analysis, 257 cases were found, the majority of them women (63%), the casuistry being approximately equally divided (48% having rural origin) in terms of the environment of origin. On average, patients were hospitalized 11.3 (±12.3) times during the analyzed period, the number of days per year and per patient being 16.5 (±15.2). The average age of the patients was 43.8 (±14.8) years, 26.5% being young patients aged ≤ 35 years. Of the patients whose brain activity was investigated (43%), 6% presented an altered EEG. In addition, 27% of the patients were brought to the hospital by ambulance or police, and 11% were referred by the UPU service. In terms of occupation, only 31% were professionally active people or students, the majority being pensioners and those without employment (56.4%).

Age of patients. Regarding the age of patients, more than a quarter of them were

young people. It is known that the incidence of suicidal ideation increases during adolescence (5). An explanation offered by some theoretical models (6), would be that some interpersonal conflicts as well as socialization difficulties would be predictors (7) and ultimately factors of suicide in adolescents. The death of a loved one has also been linked to suicidality in adolescents (5, 7). In addition, experiencing the suicide of a family member may constitute a behavioral model for already vulnerable young people (7, 8) or it could simply be viewed by a young person as a solution to a personal problem (8).

It is also interesting in this study that almost all the people in this study, with two exceptions, are younger than 65 years old. Basically, even though the study shows that almost 40% of the patients analyzed in this study are retired, they have been retired for a short time. Therefore, it is possible that the shock of not adapting to the new social condition may constitute a cause for the emergence of a suicidal state.

Risk factors for suicidal ideation and behavior among middle-aged and older adults (50-65+ years) include psychiatric disorders (especially depression), alcohol and drug use disorders, impaired physical health, chronic pain, weak social support/connection, loneliness, family problems, depression, financial problems, perceived burden, and a history of suicide attempts (9). On the other hand, protective factors against suicide include marriage, mental coping strategies, family connection, and religiosity (participation in religious activities, giving importance to religious beliefs, and activation of religious and moral objections to suicide) (9).

Religion. Regarding religion, given that it was only recorded in 37% of cases, the statistical analysis would suffer from precision. However, it is observed that Orthodox Christians had more hospitalizations (95%) than those belonging to other religious denominations, including in relation to their share in the general population. This can be explained not necessarily by a different, more efficient doctrine or set of religious rules, but especially by better psychosocial mechanisms of integration and cohesion between members of minority religious denominations who, conditioned precisely by the fact that they are a minority, in the existential desire to preserve their religious identity in a "sea" of Orthodox Christianity (representing almost 90% at the national level), develop better interpersonal social community relationships, including religious ones, with increased integrative potential, so that they manage to maintain psychological support, and not only, for the entire community, at least in times of crisis for its members.

Regardless of the religious denomination of the person, religion is generally seen as a protective factor against suicide. Some individuals with suicidal behavior have reported that developing a stronger relationship with God (10) has aided their recovery, while others have found that religion has prevented them from committing suicidal acts (11, 12). However, spirituality/religion has not always been discussed as a means of recovery (6).

Alcohol consumption and family conflicts. More than half of the patients consumed alcohol before the suicide attempt or are chronic alcohol consumers. Alcohol consumption before committing the suicide act is a known fact in the case of suicides. In the case of this study, 179 family conflicts were recorded, but it cannot be specified whether these were also based on the

patients' alcohol-related problems or whether alcohol consumption became chronic as a result of family problems.

Considering that in the case of almost 50% of the patients a psycho-stressful context was recorded, including the state of mourning, it is possible that family support was completely precarious and, moreover, the family itself was among the primary stressors that led to the suicide attempt. This can be verified and to some extent validated by the fact that almost 20% of the patients acted for demonstrative purposes, without having the intention of committing a complete suicide, but only to warn the family about their condition.

In particular, 16.3% of them were assessed by CEML or CEMRCM. As a rule, these cases committed a lethal or extremely serious aggression, based on a lethal intent, on a person in the family or outside the family, as a result of which they attempted suicide.

Impulsive temperament can lead to suicide rather than a calm one that leads to depression. From the psychological analyses included in the observation sheets it appears that impulsivity occupies an important place alongside anxiety for potentially suicidal patients. The Hamilton Depression Scale is relevant in the case of patients at risk or even attempted suicide, but the HAMA anxiety scale and the WM (Woodworth-Mathens) personality tests should not be ignored.

Frequency of mental and organic disorders associated with suicidal attempts and ideation. The study also analyzed the frequency of mental disorders associated with suicidal attempts and ideation. These disorders were considered main disorders. 127 such disease codes were found, which were used 803 times. The 20 most frequent codes (representing 15.7% of the 127 codes) had a frequency of use of 66.5%.

It is observed that recurrent depressive disorder, severe current episode with or without psychotic symptoms has the highest frequency (22% - of the total disease codes). Overall, depression, in various forms, represented around 35% of the total disease codes associated with suicidal attempts and ideation. On average, approximately 63 mental illness codes were used for each patient with suicidal attempts and ideation.

The frequency of organic diseases associated with suicidal attempts and ideation was also analyzed. These diseases were considered secondary diseases. 634 such disease codes were found, which were used 2256 times. The 20 most common codes (representing 3.15% of the 634 codes) had a frequency of use of 26.6%.

It is observed that arterial hypertension, in both its forms, presents the highest frequency (4.3% - of the total disease codes). In addition, spondylosis together with osteoporosis form 4.25% of the total disease codes. The three diseases therefore form 8.55% of the total of 634 secondary diseases associated with suicidal attempts and ideation. On average, approximately 8.8 organic disease codes were used for each patient with suicidal attempts and ideation.

Level of education. The analyses performed show an apparently lower incidence of suicidality in uneducated people (2.6%), in those with post-secondary education (1.3%) and in those with higher education (6%). In contrast, apparently, people with primary or secondary education, as well as those with secondary education, were more prone to suicidal attempts.

However, in order to obtain a correct

picture of the relationship between the level of education of the patients and their suicidal state, the data obtained must be compared with the percentages of the educational levels of Romanian citizens at national level. The comparison clearly shows that only in the case of people with primary or secondary education this remains true, the percentage of people in the analyzed population characterized by a suicidal state being double compared to their share at national level. In other words, people in the segment with primary or secondary education had the most suicidal attempts and ideation. At the opposite end, people with higher education are the least likely to commit suicide attempts or have suicidal ideation.

Period of hospitalization. According to the data obtained in this study, the seasons of the year can influence the suicidal state. The graph describing the dependence of the number of days of hospitalization on the months in which the hospitalization took place has an oscillatory profile (Fig. 1), presenting more pronounced maxima in the months of January-February (winter) and October-November (autumn-winter) and a less intense maximum in the period of May-June (spring-summer). The absolute minimum is found in the month of August (summer). This is interesting because in the specialized literature there are studies that show a seasonal distribution of the suicidal phenomenon (13, 14, 15), this being more accentuated in spring and autumn (16), i.e. overlapping only partially with the periods of hospitalization in the hospital of the patients characterized by suicidal states analyzed in this study. Therefore, the suicidal state (suicidal thoughts and/or attempts, more or less demonstrative) is, on average, approximately constant throughout the year, with the exception of summer. During the year, however, there are "explosions" in the suicidal state materialized in the complete commission of suicide. Probably only the desire to die is greater in spring and autumn, but it is present as a background state throughout the year.

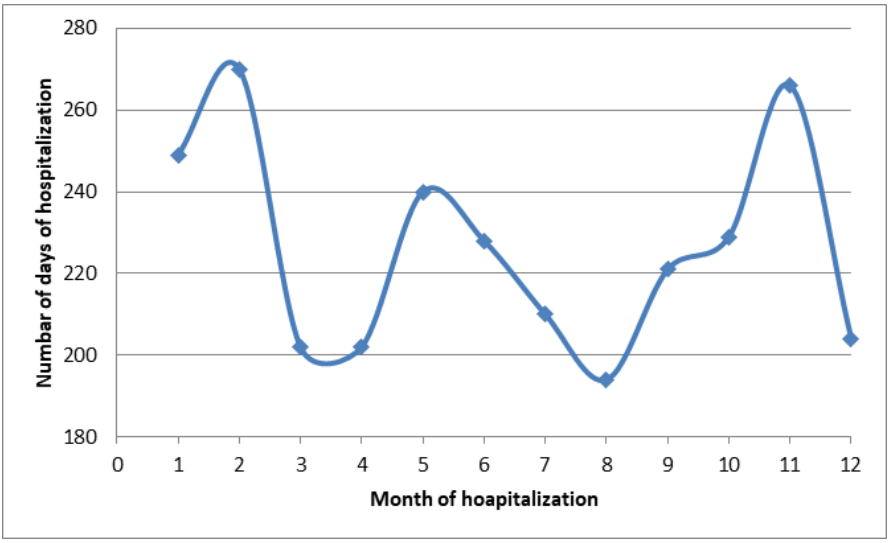

Fig. 1. Dependence of the number of days of hospitalization on the hospitalization period.

Marital status

The study of cases according to marital status is valuable, including for verifying reports that assert the positive influence of the family environment. The family status of the patients was recorded for 101 people out of the 257 investigated. Thus, 48 people were married, 29 unmarried, 15 divorced, 7 widowed, while 2 cases were cohabiting as a consensual union/cohabitation. Apparently, immediately after married people, unmarried people had the highest frequency of hospitalization. However, it is observed that, in relation to the share in the general population, unmarried people had the lowest hospitalization rate among all categories. With the exception of unmarried people and people living in cohabitation, both married people and divorced and widowed people presented higher hospitalization rates.

Methods used in suicide attempts

The main methods used in suicide attempts were intoxication, as the most common method (46.5%), followed by hanging (17.6%), chemical ingestion (8.8%) and self-mutilation (8.1%), with other methods accounting for 19% of all cases.

Drug intoxication correlates with the higher number of female hospitalizations, given that this method is one of the most common methods used by women to commit suicide. Drug intoxication allows for a longer rescue time than other more brutal methods that are usually chosen by men. Hence the higher success rate in saving female individuals, in line with their higher number of hospitalizations. The 257 patients accumulated 499 multiple suicide attempts and 159 single attempts throughout their numerous hospitalizations. Suicidal ideation was also recorded in 667 cases, and autolytic ruminations in 40 cases.

MMSE and GAFS evaluation

The MMSE (Mini Mental State Examination) is a test used to assess cognitive impairment in adults, with a maximum score of 30, with lower scores indicating more or less severe cognitive problems. The MMSE score that defines cognitive function as "normal" is usually set at 24 (17). Of the 170 people who took the MMSE, only 7.6% showed no cognitive impairment (fig. 2). However, the majority, 65.3%, were borderline normal.

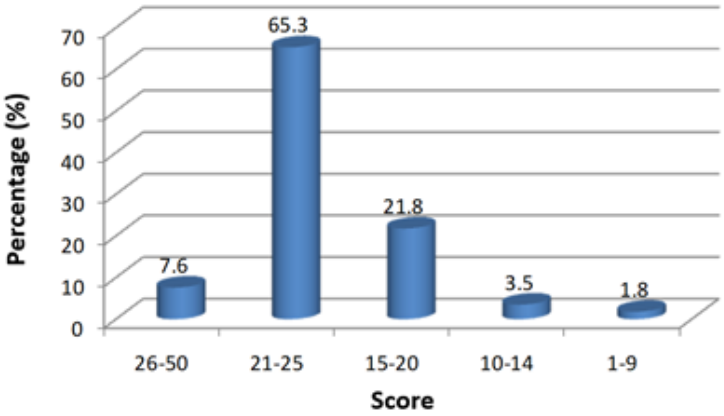

Fig. 2. Score obtained by patients in the MMSE test

The GAFS (Global Assessment of Functioning Scale) test was performed on 251 patients and shows that practically all patients presented serious symptoms ranging from severe, obsessive suicidal thoughts, communication deficits, psychosis, to delusions and hallucinations (fig. 3).

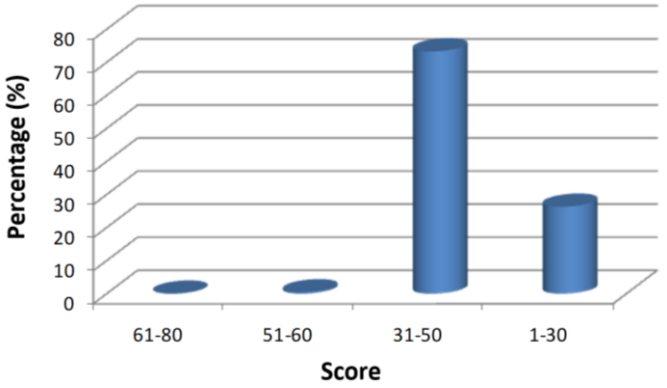

Fig. 3. Score obtained by patients in the GAFS test

Intelligence Quotient (IQ)

Only about 23% of the patients investigated had normal intellectual functioning (fig. 4). However, more than half of the patients had an IQ bordering on normality. The mean IQ was 74.85 (S.D. ± 17.26), placing them in the borderline intellectual functioning range.

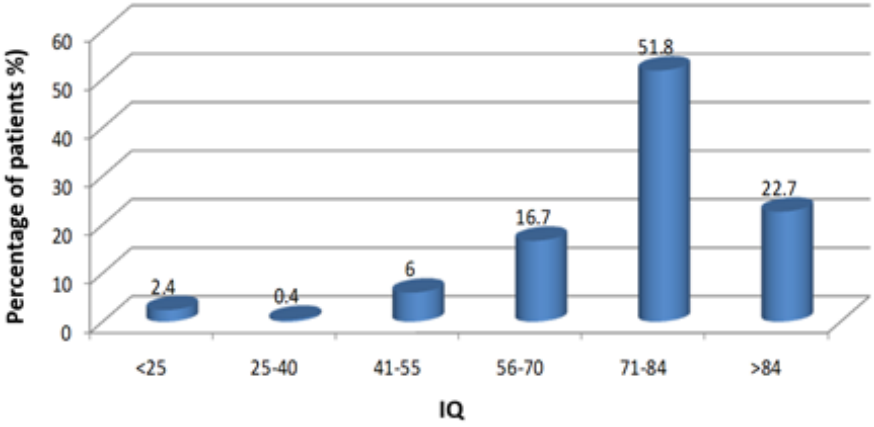

Fig. 4. The score obtained by the patients in the intelligence test

The relationship between IQ and suicidality, including suicide attempts or completed suicide, is controversial. A number of authors argue that the degree of intelligence also plays a role in the suicidal act. According to a 2004 study (18), people with high intelligence may be, overall, less adapted to different general life situations and may become more susceptible to suicide.

Also, another study from 2018 shows that poor academic performance in school, at age 16, was a robust predictor of suicide attempt in adulthood and appeared to account for the association between lower childhood IQ and suicide attempt (19).

On the other hand, another study from 2005 showed that there were no significant differences in IQ types between suicidal and non-suicidal inpatients, with logistic regression showing no evidence of an association between IQ and suicide (20).

Assessment of depression degree. In the study, the state of depression was assessed using the 21-item Hamilton Depression Rating Scale (HAM-D) which was completed and recorded for 209 patients (81.3%). The Hamilton Depression Rating Scale is used to assess the severity of depressive symptoms in patients diagnosed with a depressive disorder. The HAM-D17 contains 17 items that reflect: depressive mood, but also feelings of guilt, suicidal ideation and/or behavior, insomnia, difficulties in professional functioning, psychomotor inhibition, agitation, mental and somatic anxiety, gastrointestinal symptoms, general somatic symptoms, hypochondria, weight loss (21). Compared to the HAM-D17, the HAM-D21 contains 4 additional items: diurnal variation of mood, derealization, paranoid ideas and obsessive ideas. These items do not assess the intensity of depression and are rarely encountered in depressive syndrome, the HAM-D21 being therefore used mainly in research (21). 96.7% of the patients in the current study had severe depression and only 3.3% had moderate depression (fig. 5).

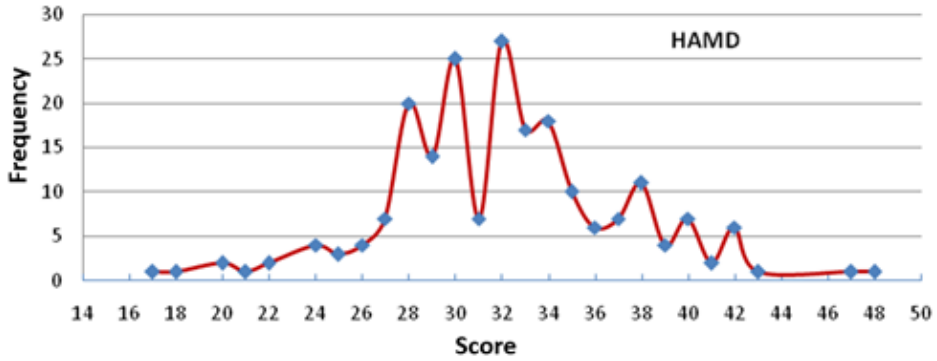

Fig. 5. The score obtained by patients in the HAMD test and its associated frequency.

From the data obtained, an association was observed between severe depression and essential hypertension for patients with suicidal ideation and behavior. Given that primary hypertension is the result of long-term psycho-organic processes, this connection can be explained by the state of stress, of inner tension that has been grinding the minds of patients for a longer period of time, generated by an increasingly accentuated depressive background. Therefore, in the case of the current study, hypertension can be considered a potential non-specific marker associated with suicidal ideation. In other words, an initially unidirectional dependency relationship

could be built between persistent stress - increased primary blood pressure - moderate/severe depression that culminates in suicidal ideation and attempt. Once built, however, the causal relationship becomes non-specific, multidirectional through persistence. Thus, the continuous presence or increased frequency of suicidal ideation can induce a state of considerable stress, leading to depression and even to the maintenance and exacerbation of cardiovascular pathology. The parameters of the relationship become interchangeable, even if their participation, influence or hierarchy present different levels in the etiology of the disease.

Medication. In this study, we also wanted to carry out a brief evaluation of the treatment addressed to both psychiatric and somatic conditions administered to patients with suicidal ideation and state. Thus, during the analyzed period, over 200 commercial names of drugs were used with a more or less high frequency, belonging to different drug classes. The top 5 used drugs were Carbamazepine, Cipralex, Rivotril, Halo-peridol, and Coaxil. Given that each patient with suicidal ideation and attempts was administered on average more than 14 different drugs, in random combinations, the evaluation of drug interaction should be a priority.

CONCLUSIONS

In this study, we performed a retrospective study, including the cases hospitalized over eight years with suicidal ideation and attempts. We have found that the depression, along with alcohol, and family conflicts were the most significant triggers of their suicide-driven ideation. Given the endurance and consistency of the suicidal ideation and attempts, we consider that increasing and diversifying the screening methods for identifying people at risk and risk factors such as depression or substance abuse, could represent one of the most direct and successful alternatives for reducing suicidal acts. The study may represent an important landmark in relation to the COVID-19 pandemic and post-pandemic period.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest, and they received no specific funding.

HIGH-FREQUENCY ULTRASONOGRAPHIC ANALYSIS IN THE EVALUATION OF THERAPEUTIC RESPONSE IN PATIENTS WITH *PSORIASIS VULGARIS* (Abstract): Plaque psoriasis is a chronic, immune-mediated disease which represents a global health problem. The main objective of the study was to determine the monitoring performance of non-invasive tests of high frequency ultrasonography (HFUS) in psoriasis vulgaris. **Materials and methods:** In a prospective interventional analytic study, we aimed to assess whether the first chronologically obtained change in psoriasis plaque assessment in monitored patients was a decrease in psoriasis plaque thickness and subepidermal hypoechoic band as compared to baseline values. The study was carried over a period of 8 weeks and included 50 patients diagnosed with psoriasis vulgaris in the Dermatology Clinic of the "Sf. Spiridon" County Clinical Emergency Hospital, Iasi. We assessed the evolution under topical (calcipotriol/betamethasone 50 micrograms/0.5mg/g gel or fluticasone propionate 0.05% cream in combination with lipolotion urea 10%) combined with systemic (Etanercept) in severe forms of disease. Target lesions of psoriasis vulgaris were analyzed by clinical examination and by HFUS. **Results:** The results showed that the first change obtained chronologically was the decrease in psoriasis plaque thickness and subepidermal hypoechoic band in the target plaque as compared to baseline values (i.e. at week 4 compared to week 0). After comparing the mean values of psoriasis plaque tegument thickness and hypoechoic subepidermal band thickness, we found that they decrease significantly both in week 4 compared to week 0 and in week 8 compared to week 4. **Conclusions.** HFUS examination allows an objective and reproducible measurement of skin thickness and is a useful technique for a non-invasive assessment of treatment efficacy in psoriasis. **Keywords:** HIGH FREQUENCY ULTRASONOGRAPHY (HFUS), PSORIASIS VULGARIS, TOPICAL THERAPY, SUBEPIDERMAL LOW ECHOGENIC BAND (SLEB), MONITORING.

INTRODUCTION

Skin ultrasonography is a non-ionizing imaging method useful in the in vivo study of skin lesions using ultrasound as a vector for imaging. Miller and Alexander reported that A-mode (Amplitude) sonography is an

effective method of determining skin thickness (1). Subsequently, in 1987, the introduction of 20-Megahertz (MHz) B-mode (Brightness) ultrasound scanning systems with axial and lateral resolution of 200 μm and 75-80 μm respectively made two-dimensional (2D) imaging possible (2). Psoriasis is a chronic immune-mediated inflammatory disease characterized by an excessive hyperproliferation of keratinocytes with extracutaneous manifestations, that affects about 1-3% of the world's population (3, 4).

The inflammatory pathology represented by psoriasis vulgaris is much more than just a skin condition and is a global health problem, with over 125 million individuals affected by this multisystemic inflammatory condition (5). Worldwide, the prevalence of psoriasis has increased from 758 cases per 100,000 population in 1990 to 812 per 100,000 population in 2017. In Europe and the U.S. 21-55% of patients have a moderate to severe form of the disease (6, 7, 8).

The examination of psoriasis plaque lesions with HFUS may indicate the following: hyperechogenic band representing the epidermis with hyperkeratosis and parakeratosis; echogenic or hypoechogenic band corresponding to the elongation of the dermal papillae as one of the most common features, hyperechogenic band given by the reticular dermis and subcutaneous hypoechogenic layer. The subepidermal hypoechogenic band is due to edema and inflammatory infiltrate in the papillary dermis. Furthermore, the overall thickness of the integument in psoriatic plaques is increased and its reduction during therapy can be objectively demonstrated (9, 10). High frequency ultrasonography (HFUS) is a proper method for psoriasis assessment without causing subjective differences in clinical scoring systems such as PASI (Psoriasis Area Severity Index), TLS (Target Lesions Score) or DLQI (Dermatology Life Quality Index) (11,12).

MATERIALS AND METHODS

The main objective of the present study was to determine the monitoring performance of non-invasive test of HFUS in psoriasis vulgaris. In a prospective interventional analytic study justified by the need to improve monitoring modalities for plaque psoriasis vulgaris, our goal was to determine whether the first chronologically obtained change in psoriasis plaque assessment in monitored patients was a decrease in psoriasis plaque thickness and subepidermal hypoechoic band as compared to baseline values. Thus, the current research aims to evaluate the contribution of imaging techniques such as HFUS in the algorithm of diagnosis and monitoring of psoriasis plaques, starting from the hypothesis that this technique may provide the possibility of establishing prognostic factors in the therapeutic management of psoriasis vulgaris.

The prospective study was carried over a period of 8 weeks (January-February 2020) and included patients diagnosed with psoriasis vulgaris in the Dermatology Clinic of the "Sf. Spiridon" Emergency Hospital, Iasi. The study was conducted on a group of 50 patients with psoriasis vulgaris composed mainly of men (78%) from urban areas (54%). The average age of the patients was 48,12 ± 14,11 years, with variations between 18 and 75 years. The parameters analyzed in the group of patients with psoriasis vulgaris were disease-related data (sex, rural/urban area), disease severity scores (PASI , DLQI) and Target Lesions Score/ TLS in weeks 0, 4, 8. Calculation of PASI scores was performed by the same examiner in weeks 0, 4, 8 with values between 0 and 72 and DLQI scores were

obtained in weeks 0 and 12 by the method of the questionnaire completed by the patient, with values between 0 and 30.

Clinical evaluation of erythematous-squamous lesions was performed by calculating a score called TLS which assesses erythema, scales and the presence of infiltration by assigning the following values: 0 - no, 1 - weak, 2 - moderate, 3 - severe. The TLS score has a maximum value of 8 and a minimum of 0 (when psoriasis plaque resolution is complete) and was clinically determined at weeks 0, 4, 8. Skin lesions with a score of 3 for scales were excluded to avoid interference with hyperkeratosis. The evaluation of the TLS therapeutic response was performed with the distribution of the therapeutic response in full resolution, major improvement, minor improvement or no response/non-responder. Others studied factors were the ultrasonographic diagnosis of the psoriasis target plaque. They were performed at weeks 0, 4 and 8 defined by the following parameters: thickness (mm) of the plaque analyzed in weeks 0, 4, 8; thickness (mm) of the hypoechogenic band in weeks 0, 4, 8; thickness (mm) of normal adjacent integument in weeks 0, 4, 8; thickness (mm) of hypoechogenic band normal integument adjacent to psoriasis plaque analyzed in weeks 0, 4 and 8.

We compared the evolution under topical and/or systemic treatment of patients with plaque psoriasis vulgaris both by classical means (clinical examination) and by non-invasive imaging techniques (HFUS). Inclusion criteria were patients clinically diagnosed and histopathologically confirmed with psoriasis vulgaris; age older than 18 years; presence of accessible lesions with cutaneous localization that can be examined using ultrasonography probe. The criteria considered for imaging selection of erythemato-squamous lesions (target lesion) required that the skin lesion examined had an active character, with onset less than 6 months; the lesion was visible and well defined. Using exclusion criteria we eliminated patients on immunosuppressive therapy other than Etanercept, on systemic corticosteroids or lithium-containing, beta-blocking medicines during the study, or 1 month prior to examination, or on other topical therapies other than those administered during study assessments; patients on current phototherapy or 6 weeks prior to study; patients with neuropsychiatric pathology; patients with the presence of tuberculosis infection, severe comorbidities, diabetes, diseases of autoimmune character, exogenous or endogenous eczema such as atopic dermatitis; patients with marked photoaging (with history of chronic sun exposure) or sun exposure within the last 6 weeks or during the study; patients with contraindications for topical treatment with calcipotriol/betamethasone gel or fluticasone propionate combinations: bacterial, viral or mycotic infections, with skin atrophy or allergic contact dermatitis due to corticosteroids or formulation constituents; pregnant or lactating patients; smoking patients.

For the study we used a high frequency ultrasound scanner (Dermascan C Cortex Technology Denmark®) with a 20 MHz transducer, 12.1 mm wavelength, with a 13 mm focus (maximum 15 mm penetrability), with 1580 m/s velocity, 0.06 mm axial resolution/0.3 mm lateral resolution, mode A of examination. 19 patients enrolled in the study received topical treatment (calcipotriol/betamethasone 50 micrograms/0.5mg/g gel in combination with lipolotion urea 10% 1application/day) or fluticasone propionate 0.05% cream in combination 2 applications/day and emulsion urea 10% 1 application/day combined with systemic treatment (Etancercept) previously initiated in severe forms of disease (31 patients).

We chose this way of dividing the topical therapy, according to the severity of the disease from a clinical point of view, quantified by PASI and DLQI score.

Patients without biological systemic therapy received topical treatment with combination of vitamin D3 analogues and dermatocorticoids (calcipotriol with betamethasone propionate gel) for their synergistic effect and obtaining a better therapeutic effect quantified by severity scores. These topical therapies (topical dermatocorticoids fluticasone propionate, combinations of dermatocorticoids with calcipotriol vitamin D3 analogues with betamethasone dipropionate) and emollient (10% urea emulsion) have been applied as recommended in current psoriasis vulgaris treatment guidelines by the American Dermatology Association as well as that of the Romanian Society of Dermatology. The research was carried out in accordance with the Declaration of Helsinki 1964 and subsequent amendments and was approved by the Ethics Committee of the "Grigore T. Popa" University of Medicine and Pharmacy Iasi and by the Ethics Committee of the "Sf. Spiridon" County Clinical Emergency Hospital, Iasi. Volunteers were informed about how the research would be carried out and gave their written consent by signing the informed consent form before the start of the study. The statistical data processing was performed using STATISTICA var. 7.0 software and Microsoft Excel.

RESULTS

In the current study, psoriasis plaque thickness values ranged in week zero between 1.70 mm and 3.77 mm, in week four between 1.34 mm and 3.56 mm, and in week eight between 1.11 mm and 3.31 mm (tab. I). The clinical and ultrasound analysis of target psoriasis plaques showed that thickness decreased continuously from one assessment in week 0 to the next in week 4 and 8.

TABLE I.
Medium skin thickness of psoriasis plaque

Variables	N	Mean	Minimum	Maximum	SD
Skin thickness plaque psoriasis (mm) in Week 0	50	2.71	1.70	3.77	0.56
Skin thickness plaque psoriasis (mm) in Week 4	50	2.50	1.34	3.56	0.57
Skin thickness plaque psoriasis (mm) in Week 8	50	2.21	1.11	3.31	0.55
N, participants number; SD, Standard Deviation					

Comparison of the mean skin thickness of the psoriasis plaque between weeks 0, 4 and 8 using the t test for repeated measurements showed that the mean thickness decreased continuously from one assessment to another:

- compared to week 0, the mean skin thickness of the psoriasis plaque decreased significantly by 0.21 mm on average in week 4, from 2.71 mm to 2.5 mm ($t=9.82$, $p <0.0000001$);
- compared to week 4, the mean skin thickness of the psoriasis plaque decreased significantly by 0.29 mm on average in week 8, from 2.5 mm to 2.21 mm ($t=7.32$, $p <0.0000001$).

The analysis of target psoriasis plaques continued in the present prospective study with the comparison of mean hypoechoic subepidermal band psoriasis plaque thickness at weeks zero, four and eight. Comparison of the mean thickness of the hypoechoic subepidermal band between weeks 0, 4 and 8 using the t test for repeat-

ed measurements showed that the mean thickness decreased continuously from one assessment to another:

- compared to week 0, the average thickness of the hypoechoic subepidermal band decreased significantly by 0.23 mm on average in week 4, from 0.60 mm to 0.37 mm ($t = 10.39$, $p < 0.0000001$);

- compared to week 4, the average thickness of the hypoechoic subepidermal band decreased significantly by 0.24 mm on average in week 8, from 0.37 mm to 0.13 mm ($t = 6.21$, $p < 0.0000001$) (tab. II).

Given that the first change obtained chronologically when assessing the target plaque of cutaneous psoriasis was the decrease in psoriasis plaque thickness and subepidermal hypoechoic band in the target plaque as compared to baseline values (i.e. at week 4 compared to week 0), after comparing the mean values of psoriasis plaque tegument thickness and hypoechoic subepidermal band thickness, we found that they decrease significantly both in week 4 compared to week 0 and in week 8 compared to week 4. It was noted that the mean thickness of the hypoechoic subepidermal band of the adjacent normal integument did not change.

Comparison of mean scores of TLS between week 0, 4, and 8 using the T test for repeated measurements (repeated assessments over time) showed that the mean score decreased continuously from one assessment the high:

- compared to week 0, the average TLS score decreased significantly by 3.42 points on average in week 4, from 6.94 points to 3.52 points ($t = 21.82$, $p < 0.0000001$);

- compared to week 4, the mean TLS score decreased significantly by 2.96 points on average in week 8, from 3.52 points to 0.56 points ($t = 17.04$, $p < 0.0000001$).

TABLE II.

Comparison of the average thickness of the hypoechoic subepidermal band in week 0, 4 and 8

Comparisons between	Mean 1	SD 1	Mean 2	SD2	N	Difference	SD of the difference	t	p
Week 0 with week 4	**0.60**	0.34	***0.37***↓	0.29	50	0.23	0.15	10.39	***<0.0000001***
Week 0 with week 8	**0.60**	0.34	***0.13***↓	0.24	50	0.47	0.35	9.48	***<0.0000001***
Week 4 with week 8	**0.37**	0.29	***0.13***↓	0.24	50	0.24	0.28	6.21	***<0.0000001***
N, number of participants; SD, Standard Deviation									

In order to study the relationship between the clinical and ultrasonographic appearance of the psoriasis target plaque Pearson r correlation coefficients were calculated, being considered significant those coefficients that were at a significance threshold $p < 0.05$. The analysis of the correlations between the clinical and ultrasonographic appearance of the psoriasis target plate showed that:

- in the first week, no significant correlations were found; from the fourth week, some small but statistically significant direct correlations were found, as follows:

- between the skin thickness of the psoriasis plaque from week four and TLS from week four ($r = 0.3970$, $p = 0.004$), between the skin thickness of the psoriasis plaque from week eight and TLS from week eight ($r = 0.3432$, $p = 0.015$); between the thickness of the hypoechoic subepidermal band at week eight and the TLS at week eight (r

= 0.3475, p = 0.013).

The results revealed that the average PASI scores decreased significantly from one assessment to another, as follows:

- an average decrease of 5.66, from 23.62 in week 0, to 17.96 in week 4, (t = 7.44, p <0.0000001);
- an average decrease of 4.96, from 17.96 in week 4, to 13 in week 8, (t = 8.59, p <0.0000001);
- an average decrease of 4.3, from 13 in week 8, to 8.7 in week 12, (t = 8.82, p <0.0000001).

Similarly, the average DLQI scores decreased significantly from one assessment to another, showing that:

- an average decrease of 10.48, from 23.08 in week 0, to 12.6 in week 8, (t = 12.48, p <0.0000001);
- an average decrease of 2.54, from 12.6 in week 8, to 10.06 in week 12, (t = 11.96, p <0.0000001).

Significant direct correlations were not obtained between skin thickness of psoriasis plaque or hypoechoic subepidermal band and PASI score.

DISCUSSION

HFUS of the integument or nail apparatus can be used in the evaluation of response to local and/or systemic treatment (13, 14, 15). In a pilot study of 30 patients with psoriasis vulgaris compared to 10 healthy volunteers who used topical clobetasol propionate 0.05% foam differently (one arm of patients with psoriasis vulgaris applied twice daily for 14 days, the second arm applied once daily for one month, and volunteers once daily for four weeks) Lacarrubba *et al*. reported reduced psoriasis plaque thickness when monitoring treatment response with 20 MHz HFUS (16).

This resulted in equal values of integument thickness to that of adjacent healthy skin in all treated plaques, with no differences between the two psoriasis patient groups, and no sonographic variations in skin thickness were observed in the healthy group at the end of the study (16). In contrast to Lacarruba's study, in the current study we evaluated the therapeutic response not only under topical treatment (Fluticasone Propionate 0.5g/g cream or Calcipotriol/Betamethasone dipropionate 50 micrograms/0.5 mg/g gel and 10% Urea Emulsion) but also systemic, with 31 patients also under biological therapy with Etanercept. Similarly, in the 20 MHz ultrasonographic examination using Dermascan C® the study published by Micali *et al.* showed that at the 15-day examination, psoriasis plaque values were reduced by 33.5% in Etanercept-treated patients, by 63.6% at 30 days, and by 79.3% at 60 days. In total, after 60 days of treatment, 23 of the 42 psoriasis plaques analyzed showed complete normalization (13).

Subepidermal hypoechoic band can also be found in other inflammatory conditions such as atopic dermatitis or contact dermatitis (17). As a result, patients with these pathologies were excluded. In addition to the Subepidermal Low Echogenic Band (SLEB), in psoriasis we may detect thickened entry echo and streaky which is perpendicular to the entry echo shadows caused probably by air bubbles trapped between the scales (18). HFUS of the normal skin shows a clear separation of the skin layers (19). Camerota *et al*. argue that entry eco is due to the difference in acoustic impedance between gel and skin (20). The average epidermal thickness in healthy individuals is 0.6 mm, being between 0.1-0.8 mm (21).

For inflammatory dermatoses like psoriasis vulgaris, eczema, atopic dermatitis as well as in mycosis fungoides, similarly to the skin elastosis SLEB may be easy to

identify (22, 23). Maria C *et al*. (24) compared the efficiency of 20 MHz skin ultrasonography but also 40 MHz conventional ultrasonography in the assessment of 16 plaques psoriasis in three consecutive patients. The measurement was made at baseline and after hydrocortisone acetate 1% ointment six-week application. In contrast with our study parameters (total psoriasis plaque thickness including epidermal and dermal thickness and hypoechogenic band), their parameters were represented by epidermal and dermal thicknesses for gray-scale ultrasonography. Their results indicated that epidermal thickness was significantly reduced with 20 MHz and 40 MHz sonography, while dermal thickness varied insignificantly with 20 MHz and 40 MHz sonography. Gutierrez *et al*. (25) have showed that dermal thickness has been found to be correlated with disease severity measured using PASI score and other scales assessing the severity or extent of disease (11). Similarly, Fernando Alfageme (26) indicated that in a multicenter study HFUS examination showed a reduction in plaque thickness and Doppler signal intensity in the dermis of patients treated with infliximab.

One limitation of the study is the lack of biological and hematological data such as inflammatory syndrome indicated by Erythrocyte sedimentation rate (ESR) or imagistic tests like joint x-rays which can facilitate the diagnosis of severe form of psoriasis accompanied by psoriatic arthritis.

CONCLUSIONS

HFUS examination allows an objective and reproducible measurement of skin thickness and is a useful technique for a non-invasive assessment of treatment efficacy in psoriasis. Psoriasis plaque thickness and subepidermal hypoechoic band thickness can be markers of progression and therapeutic efficacy. The efficacy indicators of therapy objectified by HFUS are decreases in epidermal and dermal thickness and disappearance of the hypoechoic band. In the current study, the first chronological change obtained in the assessment of the target plaque of cutaneous psoriasis was a decrease in the thickness of the psoriasis plaque and the subepidermal hypoechoic band in the target plaque as compared to baseline values (i.e. at week 4 versus week 0), and after comparing the mean values of psoriasis plaque integument thickness and hypoechoic subepidermal band thickness, we found that they decrease significantly both in week 4 as compared to week 0 and in week 8 as compared to week 4.

CONE BEAM COMPUTED TOMOGRAPHY ASSESSMENT OF CRANIOMANDIBULAR DISORDERS. A PROSPECTIVE STUDY FOR OSSEOUS COMPONENTS AND RISK FACTORS (Abstract): Craniomandibular disorders (CMD) are a series of clinical dysfunctions on the level of masticatory muscles, temporomandibular joint (TMJ) or both. Our aim was to use CBCT imagery to evaluate the morphology of the TMJ's components, to document any variations, and to corelate this data with the anatomy of the developing TMJ and the risk factors of the severity of CMD in patients from NE Romania. **Materials and Methods:** Our prospective study was conducted on 105 patients (70.5% were females and 53.3% were aged 26 to 45 years). All patients were carefully examined, underwent orthopantomogram and cone beam CT scans and were categorized according to the current diagnostic criteria for TMJ disorders. Group 1 (73 patients) were identified with symptomatic CMDs (clicking / crepitation, joint pain, muscle pain, limited mouth opening and non-harmonic movement of the jaw), while the remaining 32 patients represented Group 2 with asymptomatic presentation. **Results:** Linear measurements of TMJ spaces displayed statistically significant differences with age in the intervals of 18-25, 26-35 and 46-55years, while in the age groups of 36-45 and over 55 years, the results were similar on the right *vs.* left side. In Group 1, left-right differences were significantly greater in females (0.2265 ± 0.04029) compared to males (0.2067 ± 0.03152), with the highest amplitude being observed in the 18-25 and 26-35 age subgroups. The left-right differences remained statistically significant between the two groups even in comparative analysis of patients with/without intense weekly physical activity and in those with/without parafunctions (grinding, thumb sucking, or tongue thrusting). **Conclusions:** The severity of CMDs is more common in young age females. Oral status and morphology represent a significant risk factor for TMJ disorders.
Keywords: CRANIOMANDIBULAR DISORDER, CBCT, TEMPOROMANDIBULAR JOINT, CONDYLE, GLENOID FOSSA.

INTRODUCTION

The temporomandibular joint (TMJ) is defined as a ginglymo-arthrodial synovial joint consisting of an articular disk, fibrous capsule, articular eminence, synovial membrane and fluid, and associated ligaments.

The mandibular condyle is the inferior part of the articular surface of the TMJ, whereas in the superior part of the articular surface one finds the articular eminence of the temporal bone and the mandibular fossa (glenoid fossa). This joint is not only pivotal for hinging and gliding movements of the mandible across all spatial planes, but it also plays a vital role in maintaining the dynamic of mandible (1, 2).

The volume and size of the TMJ can be associated with the final dimensions of the mandibular arch and the relationship between the two arches. Also, the evaluation and the assessment of the volume and morphology of condyle are of utmost importance (3). Nowadays, there is no objective criterion for the ideal position of the mandibular condyle within the glenoid fossa. When the posterior joint space width is less than the anterior joint space, the condyle is retracted, and when the anterior joint space is greater, the condyle is protracted (4).

Craniomandibular disorder (CMD) is a general term for a group of diseases affecting temporomandibular joint (TMJ), masticatory muscles, and/or the surrounding tissues (5, 6). The main symptomatology is represented by muscle pain in the head and neck region, noise and pain in the temporomandibular joint, and limitation of the mandibular mobility. Other possible symptoms encountered are headache, posterior neck pain and dental pain (7). CMD is the second most common musculoskeletal disorder which leads to pain and disability (8, 9).

The recent advancements in three-dimensional (3D) technology, especially for osseous components, is represented by cone beam computed tomography (CBCT) that have enabled us to analyze the TMJ in a more comprehensive manner than before (10).

The aim of this research was to use CBCT imaging modality to evaluate the morphology of the mandibular condyle, glenoid fossa, other TMJ components and to document any morphological variations. The data obtained may provide valuable information on the anatomy of the development of the TMJ and joint spaces.

MATERIALS AND METHODS

Study design. A prospective study was conducted on patients 105 patients, of which three-quarters were women (70.5%), and half were aged between 26 and 45 years (53.3%). Among them, 73 patients (69.5%) were identified with symptomatic CMDs (clicking / crepitation, joint pain, muscle pain, limited mouth opening and non-harmonic movement of the jaw), while the remaining 32 patients (30.5%) represent Group 2 of asymptomatic patients.

All patients were carefully examined, underwent orthopantomogram (OPG) and CBCT scans, and were categorized according to the current diagnostic criteria for TMJ disorders. Full-volume CBCT scans using a Green X CBCT (VATECH) machine were taken at a centric relation position with the patient's mouth, closed in the natural head position, from October 2023 to September 2024. These CBCT images were taken at 90 kV and 8 mA with a volume size of 24 x 17 cm^2, a voxel size of 0.4 mm, and an exposure time of 3.7 s.

The inclusion criteria for the study were patients who have: been at least 18 years of age; filled written informed consent; completed the questionnaire PHQ-9 Patient Health Questionnaire-9 (7); and completed the personalized merged version of questionnaire TMD-Pain Screener (2).

The exclusion criteria for the study were patients who have/were: refused to participate in the study; non-cooperative; systemic joint disorders; neurological diseases; psychiatric diseases; cervical spine alterations; facial paralysis; previously diagnosed temporomandibular joint (TMJ) pathology.

Measurements. All CBCT images were oriented and analyzed using a digital software RadiAnt-DICOM Viewer version 2024.1. The axial slice of 0.4 mm was selected for measuring medio-lateral and antero-posterior dimensions. The joint spaces, eminence height and eminence inclinations were measured using sagittal slice of thickness of one mm from medial condyle to orbital.

The eminence inclination was measured using two methods: the best-fit (bf) line method and top-roof (tr) line method. The best-fit line method measures the angle between Ebf (eminence best-fit) and F (Frankfort), top-roof line method measures the angle between Etr (eminence top-roof) and F.

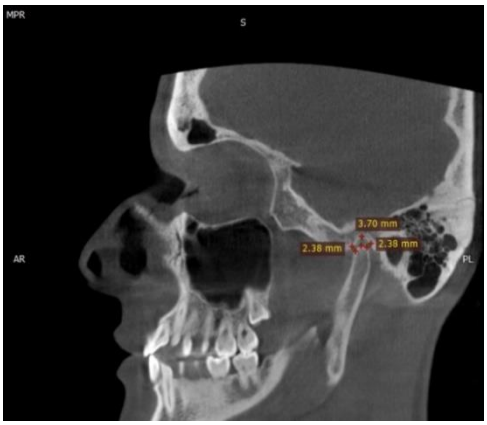

Fig. 2. Measurement of Sjs - Superior Ajs -Anterior joint space, and Pjs – Posterior joint space.

In sagittal plane, the thickness of the glenoid fossa was defined as the distance between the outer cortical outline and the inner cortical outline.

Metric evaluation of morphology of the mandibular condyle and glenoid fossa, including its condylar height, width, length, roof of glenoid fossa (RGF) thickness, anterior, posterior, and superior joint space, and volume of the condyle were recorded.

Fig. 1. Measurement of ML - Medio-Lateral joint space, width of condyle, a nd AP - Antero-Posterior width of condyle.

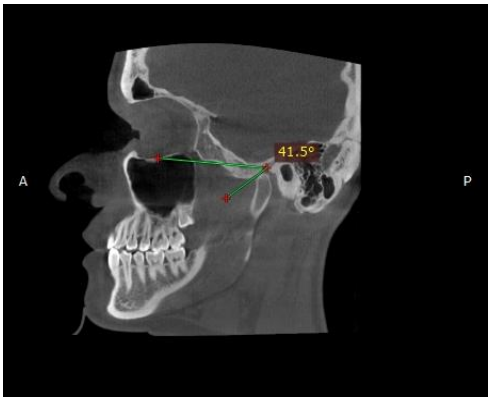

Fig. 3. Measurement of EBFA - Eminence image Best Fit Angle, ETRA - Eminence Top sagittal Roof Angle, F-Frankfort horizontal line.

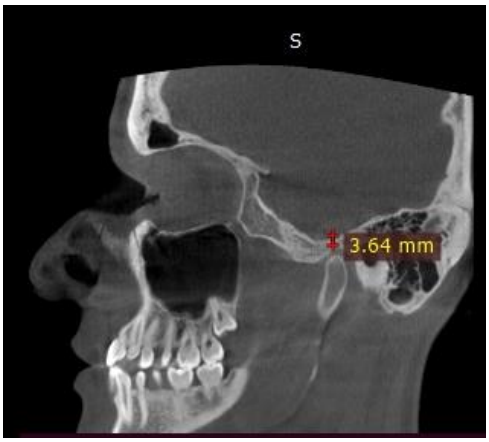

Fig. 4. Cone beam computed tomography image and schematic representation of the sagittal view showing glenoid fossa roof thickness measurement between the outer and inner cortical outline of the bone.

A 2D sagittal slice with a clear appearance of the condyle and glenoid fossa was selected. The superior-most portion of the mandibular condyle was denoted as superior mandibular condyle (SCo). Two points, one posterior and one anterior, on either side of the condyle were selected as posterior-most mandibular condyle point (PCo) and anterior-most condylar point (ACo). From this selected sagittal slice, the condylar length was measured.

The areas of maximum convex curvature on either side of the condyle, in the coronal section, were chosen as the medial condyle (MCo) and lateral condyle (LCo). Condylar width was measured as the linear distance between the mandibular lateral and medial poles.

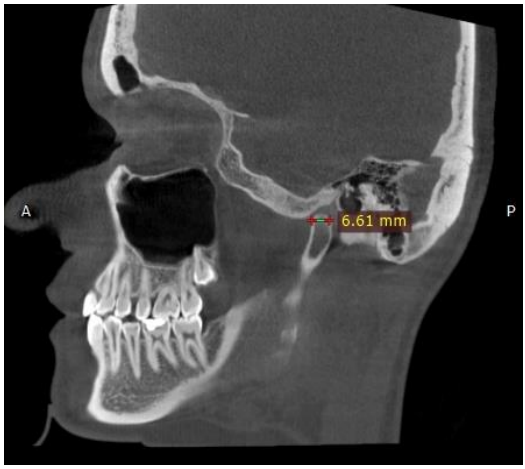

Fig. 5. Cone beam computed tomography image in sagittal view of the condylar length in the anteroposterior direction. (ACo, anterior-most condylar point; PCo, posterior-most mandibular condyle point; SCo, superior mandibular condyle)

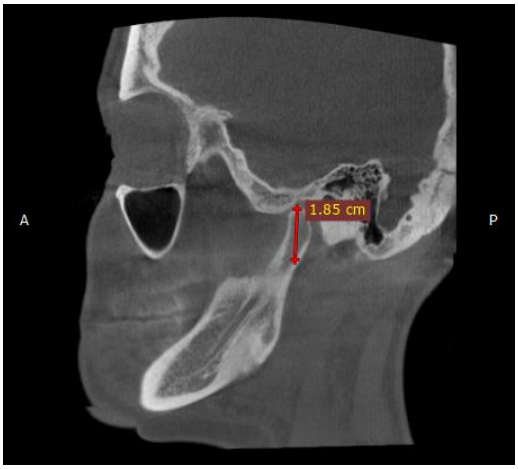

Fig. 6. Cone beam computed tomography image and schematic representation of the sagittal view showing condylar height measurements. (Inf Sig, inferior-most point of the sigmoid notch; SCo, superior mandibular condyle)

The **intercondylar distance** in the context of the temporomandibular joint (TMJ) refers to the space between the medial or lateral femoral condyles.

Fig. 7. Cone beam computed tomography image tomography of intercondylar distance.

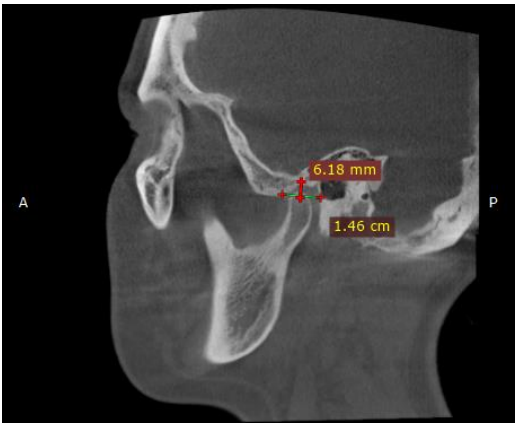

Fig. 8. Cone beam computed tomography image of the glenoid depth.

Data analysis. The data were centralized in *SPSS 24* databases and processed with suitable statistical function. Both descriptive and analytical methods were used. We compared average percentages between various genders and severity levels using the Pearson Chi-squared test, with a significance level of error set at 95%. We also performed the Mann-Whitney test (parametric) to compare two samples or groups, with low numbers of individuals in each group, which are not normally distributed, and where the data are continuous.

RESULTS

Comparative study of the parameters investigated in the sample of patients with CM dysfunctions versus asymptomatic patients

A cohort of 105 patients was investigated, of which three-quarters were women (70.5%), and half were aged between 26 and 45 years (53.3%). Among them, 73 patients (69.5%) were identified with CM dysfunctions (Group 1), while the remaining 32 patients (30.5%) made the Group 2 asymptomatic patients. Specifically, Group 1 displayed a heterogeneous distribution across age groups, covering the entire range from 18 to 75 years, whereas the vast majority of patients in Group 2 - asymptomatic patients (75.0%) were young adults aged between 26 and 45 years. Most patients with CM dysfunctions exhibited only mild dysfunctions (80.8%), with 19.2% of cases identified as having moderate dysfunctions (tab. I).

Additionally, the values of the differences between the left-right symmetric measurements across the entire sample (general statistical characterization) are presented in table II.

The study of the correlations between left-right measurement differences and clinical parameters of the patients

The first parameter considered for potential correlations was the patients' age. The only measurement found to be correlated with age was the articular slope - specifically, the left-right difference in its values - which showed a weak but positive and statistically significant correlation with patient age ($r = 0.222$) (tab. III).

TABLE I.

Demographic and clinical characteristics of the samples investigated

		SAMPLE				Total		Pearson Chi-squared test
		Group 1 -CM Dysfunction		Group 2 - Asymptomatic patients				
		N	%	N	%	N	%	
Gender	male	21	28.8%	10	31.3%	31	29.5%	$Chi^2 = 0.066$

DISCUSSION

The accuracy of CBCT for linear measurements was confirmed in various studies by Lascala *et al.* (10) and Soumalainen *et al.* (11). Furthermore, Lascala *et al.*, consider that CBCT images underestimate the actual distances on the base of the skull between different points and are accurate for linear measurements of these structures (10). Soumalainen *et al.*, stated that the error in linear measurement and evaluation using CBCT technique was lower than that of CT (11).

Dalili *et al.* in their study, concluded that males have larger linear measurements of joint spaces in comparation with females, especially the posterior and the superior spaces (12).

In our Group 1 (CM dysfunction), statistically significant differences were observed between right and left measurements, with the values recorded on the right side being statistically significantly higher than those recorded on the left side. Among male patients, although the measurements on the right side were also higher than those on the left, the observed differences did not reach statistical significance; however, among female patients, the differences were greater and statistically significant (tab. II).

The results of our study are aligned with other studies, wherein a significant difference was observed between the two genders when linear dimensions of posterior and superior joint spaces were compared (13). Another explanation could be due to the difference in the overall size of tem-

poral fossa and mandibular condyle in males, because of sexual dimorphism (14).

In our study, linear measurements of the joint spaces displayed significant differences with age. The same statistically significant differences were also found in the age groups 18-25 years, 26-35 years, and 46-55 years; in patients aged 36-45 years and those over 55 years, the measurements on the right and left sides were similar (tab. III). This agrees with the results of a study by Alexiou *et al*. (15), who concluded that linear measurement of the joint spaces decreases with age.

In our study, the volume of the condyle was significantly greater in males (tab. II, tab. III) and was aligned with the results of Tadej *et al*. (16), the latter relating the overall size of the mandibular condyle to sexual dimorphism.

Comparing the measurements of the posterior and superior space among left and right sides, a significant difference was observed in both genders. This asymmetry observed in our study in the condylar position within the left and right sides of glenoid fossa could be explained by the presence of a preferred side for mastication, as also stated by Blaschke and Blaschke (17) and by Tecco *et al*. (18). Moreover, the overall asymmetry in the joint structure, that we also emphasized, must be due to the preferred side of chewing among the subjects with CM disorders, in their effort to mitigate discomfort, but with consequences in altered morphology and volume (19).

The volume of the condyle decreased with age, and this was significant in females. Our findings are also supported by Takayama *et al*, who reported it in both males and females; volumetric and morphologic changes in TMJ being both adaptive and degenerative over a long period of time (20).

In Group 1 these left-right differences are statistically significantly greater in females (0.2265 ± 0.04029) compared +to males (0.2067 ± 0.03152). The largest differences were observed in the 18-25 and 26-35 age groups (tab. III), reconfirming Chaurasia *et al*. who noted that the condylar height and width are maximum between 20 and 30 years of age, followed by a gradual reduction with age (21).

The significant difference among the right and left sides observed in our study suggested that the right side has a more posteriorly placed fossa, a narrow glenoid fossa width, and greater inclination of the anterior wall, while the left condyle has increased condylar width and vertical inclination.

We observed also significant differences between the right and left side measurements when separately analyzing patients with mild and moderate dysfunctions, as well as those with mild or moderate depression. The differences between right and left side measurements remained statistically significant even in separate analyses of patients with or without parafunctions (tab. II). Bruxism is one of the most common parafunctions, consisting in repetitive jaw muscle activity, clenching or grinding of the teeth and/or bracing or thrusting of the mandible. It is generally accepted that extreme bruxing activity may lead to a breakdown in the stomatognathic system, orofacial pain and TMD, thus raising the need for reliable and validated screening tools, and structured clinical examination (22).

Our study highlighted the relationship

between morphology of TMJ in symptomatic and asymptomatic TMDs. We can state that craniomandibular disorders (CMDs) is a significant concern that should be screened and addressed accordingly, especially in the population at greater risk, and CBCT can be a valuable diagnostic aid in the evaluation of various morphometric analysis of the TMJ.

CONCLUSIONS

Our research proved there was a significant variation in the linear condylar measurements of width and volume between the left and right side of the temporomandibular joint (TMJ), which leads us to state that each condyle should be evaluated and assessed as a separate entity prior to any treatment.

According to our results, the severity of the craniomandibular disorder is more common in females, and at a young age. Oral status and joint morphology have been established as a significant risk factor for TMJ disorders, apart from parafunctional habits (grinding, thumb sucking, or tongue thrusting), intense physical activity, and/or pathologic occlusion.

This study advocates an increased awareness in the medical community for the relationship between temporomandibular joint (TMJ) screening based on CBCT and the role of morphological and external factors for an efficient future therapeutic approach.

ETHICS

Institutional Review Board Statement: The study was conducted in accordance with the Declaration of Helsinki and approved by the Ethics Committee of Grigore T. Popa University of Medicine and Pharmacy of Iasi (271/14.02.2023) for studies involving humans.

Informed Consent Statement. Informed consent was obtained from all subjects involved in the study.

CONFLICT OF INTERESTS AND FUNDING

The authors declare no conflict of interests.

Our study was supported by Grigore T. Popa University of Medicine and Pharmacy Iasi, Romania, as part of the doctoral research program of the first author, V.B.

DETERMINATION OF HEART RATE VARIABILITY, A POSSIBLE MARKER FOR ASSESSING INTRINSIC CAPACITY (Abstract): The assessment of heart rate variability (HRV) parameters is a non-invasive method of multidimensional evaluation of geriatric patients, independent of complex geriatric and clinical-biological assessment, with an impact on the early identification of nutritional disorder, cognitive status, psycho-emotional status, frailty, cardiovascular mortality risk, as well as functional disorders and maintaining quality of life. **Aim:** To determine HRV parameters and their role in assessing intrinsic capacity in old patients. **Materials and methods:** We determined HRV in a group of 83 patients over the age of 65 who were admitted to the Geriatric Clinic of the Dr. C. I. Parhon Hospital in Iasi, and we also performed a complex geriatric assessment by evaluating cognitive status (MMSE - Mini-Mental State Exam), nutritional status (MNA - Mini Nutritional Assessment), psycho-emotional (GDS - Geriatric Depression Scale), risk of falling (Downton Scale), the presence or the absence of the urinary incontinence, as well as determining body composition using bioimpedance. **Results:** The average age was 75.64 ± 6.64 years with a median of 75 years, most patients being women (63.9%). The distribution by age group shows that most patients were between 65 and 74 years old (48.2%), falling into the young old category; of these, 60% were female. Low scores on the MNA, as well as low muscle strength, body mass index, bone mass, visceral fat values or urinary incontinence are correlated with decreased heart rate variability (HRV) parameters. The presence of anemia or depressive symptoms is associated with reduced levels of HRV parameters. **Conclusions:** Data obtained support the existence of a causal relationship between heart rate variability (HRV) and a number of factors, both dependent on the patient's clinical-biological status and geriatric profile, and independent of it. Early identification of these factors in the old population is essential for preventing adverse changes in body composition, appearance in psycho-emotional disorder, urinary incontinence, as well as for mitigating their impact on autonomy and quality of life. **Keywords**: HEART RATE VARIABILITY, INTRINSIC CAPACITY, BODY COMPOSITION, NUTRITIONAL DISORDER, OLD PATIENTS.

INTRODUCTION

Assessing intrinsic capacity in all five dimensions (functional status, cognition, vitality, sensory functioning, and psycho-emotional assessment) is a central concept in modern geriatrics (1, 2, 3). This is achieved either through clinical- biological assessment or by using complex geriatric assessment scales: Mini-Mental State Examination (MMSE), Mini Nutritional As-

sessment (MNA), Geriatric Depression Scale (GDS), risk of falling - Downton Scale (3). These diagnostic methods are time-consuming and energy-intensive, limiting the development of a personalized treatment plan. Therefore, in the context of contemporary medical practice, the integration of advanced technological innovations contributes to the optimization of diagnosis and monitoring of therapeutic interventions (2).

Determining heart rate variability is a modern, non-invasive method that consists of identifying normal fluctuations in the interval between two successive heartbeats-RR intervals - a mechanism controlled by the autonomic nervous system (ANS) (1, 4, 5). Heart rate variability (HRV) parameters are classified into several main domains, namely the time domain (e.g. SDNN standard deviation of intervals, SDANN standard deviation of average intervals for each 5-minute segment, RMSSD mean square of successive interval differences) and the frequency domain (Power - ULF, VLF, LF, HF, Absolute power of ultra-low, very low, low, and high frequency bands, Peak - ULF, VLF, LF, HF, Peak frequency of ultra-low, very low, low, and high frequency bands, LF/HF Ratio between low and high frequency power, each providing complementary information on autonomic heart rate regulation) (1).

The assessment of these parameters provides information about the sympathetic-vagal balance, estimation of cardiovascular and overall mortality risk, as well as identification of neurocognitive function decline and the nutritional disorders, systems that are part of the assessment of intrinsic capacity (6, 7, 8, 9, 10). A high level of HRV is considered a sign of autonomic balance, physiological resilience, and adaptability, while low HRV indicates autonomic dysfunction, chronic stress, inflammation, or increased cardiovascular risk (11, 12, 13, 14, 15).

In old patients, age-related changes and chronic comorbidities frequently lead to a reduction in parasympathetic activity and, implicitly, to a decrease in HRV, which is associated with an increased risk of developing, and increased mortality. Therefore, the need to integrate heart rate variability assessment into geriatric clinical practice can lead to the collection of fundamental data on multidimensional health status, as well as medical outlook, prognosis, and quality of life (16, 17, 18, 19).

MATERIALS AND METHODS

We present a prospective study that started in January 2024, from which we present the preliminary data collected in January - October 2024, on a group of 83 patients, aged over 65, hospitalized in the "Dr. C.I. Parhon" Clinical Hospital Iasi.

The exclusion criteria were as follows: age under 65 years, absence of informed consent, unavailability of relevant clinical or biochemical data, severely compromised functional status (patients bedridden or unable to maintain orthostasis which prevented the assessment of body composition by bioelectrical impedance analysis), presence of an active implantable device (e.g. pacemaker).

All patients enrolled in the study underwent intrinsic capacity assessment using the following scales: MMSE, MNA, GDS, fall risk - Downton scale, the presence or the absence of the urinary incontinence, as well as cardiovascular assessment (EKG, Holter EKG, echocardiography) (20, 21, 22). We also determined muscle strength in both upper limbs using a dynamometer and extracted data on biochemical levels to assess nutritional status (total protein level, hemoglobin level). Furthermore, all patients underwent body composition assess-

ment using the Tanita BC-545N weighing scale bioimpedance device.

Muscle strength was assessed with a dynamometer, and values were interpreted according to sex and age, with specific thresholds for men and women, defining normal, low, or high values (23). For men aged 65 to 69, normal muscle strength ranged from 28.2 kg to 44.0 kg, and for those aged 70 to 99, from 21.3 kg to 35.1 kg. For women aged 65 to 69, normal muscle strength ranged from 15.4 kg to 27.2 kg, and for those aged 70 to 99, from 14.7 kg to 24.5 kg. Values below the lower limit were considered low, and those above the upper limit were considered high (23).

Cognitive status was determined using the MMSE scale (0-30 points), with normal cognitive function between 25-30, mild impairment between 20-24, moderate impairment between 10-19, and severe impairment below 10 points (24).

Nutritional assessment was based on the MNA questionnaire (24-30 indicates normal nutrition, 17-23.5 risk of malnutrition, <17 malnutrition) (24), as well as on body mass index, with standard categories of underweight (18.5 kg/m²), normal weight (18.5 and 24.9 kg/m²), overweight (25 and 29.9 kg/m²), between 30 and 34.9 kg/m² obesity grade I, between 35 and 39.9 kg/m² obesity grade II, and values above 40 kg/m² morbid obesity (25).

Biochemical parameters were taken from recent data (≤ 7 days), with normal ranges for total protein (66-87 g/L) and hemoglobin (11.5-15.7 g/dL), values below and above the limits being considered abnormal.

Visceral fat was measured by bioelectrical impedance using Tanita BC-545N, classifying values as normal (1-12), high (13-19), or very high (>19), adjusted for age, sex, height, and patient profile.

Emotional state was assessed using the 15-item Geriatric Depression Scale (GDS), considering scores below 5 as normal, 5-8 as mild depression, 9-11 as moderate depression, and above 11 as severe depression (26).

Data on urinary incontinence were taken from the patient's medical history or observation sheet and were noted as present or absent.

The completing of the questionnaires was done after obtaining the informed consent of the patient, being made by the same trained medical team.

The data were collected by a geriatric team and were analyzed using SPSS 18.0 software. ANOVA Test, Chi-square Test and Paired T-test, Kruskall-Wallis and Pearson correlation for quantitative analyze where performed. The statistical significance was defined in 95% interval of confidence ($p < 0.05$).

RESULTS

The patients included in the study had a mean age of 75.64 ± 6.64 years, with a median age of 75 years. Most of the subjects were female (63.9%). The distribution by age group showed that 48.2% of participants fell into the "young old" category (65-74 years), 39.8% into the "adult old" category (75-84 years), and 12% were over 85 years old. Most patients included in the study had relatively balanced cognitive characteristics of their psychoemotional status (tab. I).

Approximately 30% of subjects had reduced muscle strength in one of their upper limbs, either dominant or non-dominant. In terms of body composition, most patients had an increased body mass index (BMI), thus falling into the overweight category, and about 70% had a high percentage of total body fat.

TABLE I.
Characteristics of the analyzed patients.

Parameter (Mean ± SD, Median (IQR) / No, %)	Value
MNA	23.5 ± 3.69, 24 (21-26)
MMSE	26.47 ± 3.62, 27 (25-29)
GDS	5.8 ± 3.34, 5 (3-9)
Muscle force - right arm	21.7 ± 9.41, 20.8 (14.1-27.8)
Muscle force - right arm (Category)	
Low	24 (28.9%)
Normal	52 (62.7%)
High	7 (8.4%)
Muscle force - left arm	20.87 ± 8.85, 19.8 (14.4-26.9)
Muscle force - left arm (Category)	
Low	26 (31.3%)
Normal	51 (61.4%)
High	6 (7.2%)
Total fat	34.72 ± 8.68, 34.3 (29.1-40.9)
Total fat (Category)	
Low	2 (2.4%)
Normal	23 (27.7%)
High	58 (69.9%)
BMI	28.97 ± 5.72, 28.3 (25.9-31.9)

Nutritional Status Assessment

Based on the geriatric assessment and MNA scores, Spearman's correlation analysis (ρ) revealed positive associations between the nutritional score and certain parameters of heart rate variability: Variability ($p = 0.046$; $\rho = 0.220$), SDNN ($p = 0.047$; $\rho = 0.219$), SDANN ($p = 0.015$; $\rho = 0.267$), and ULF ($p = 0.013$; $\rho = 0.271$) (fig. 1).

Total protein values were positively correlated with SDANN ($p=0.046$; $\rho = 0.221$), and hemoglobin showed positive correlations with Variance and SDNN ($p \approx 0.046$-0.047; $\rho \approx 0.218$-0.220), suggesting an association between nutritional status and heart rate variability parameters (fig. 2).

Body composition assessment, as part of nutritional status analysis, revealed significant positive correlations between bone mass and LF ($p = 0.025$; $\rho = 0.245$) and HF ($p = 0.016$; $\rho = 0.263$), indicating an association of higher bone mass with increased sympathetic and parasympathetic autonomic activity. Body mass index (BMI) was positively correlated with HF ($p = 0.044$; $\rho = 0.222$), suggesting a similar relationship with parasympathetic activity.

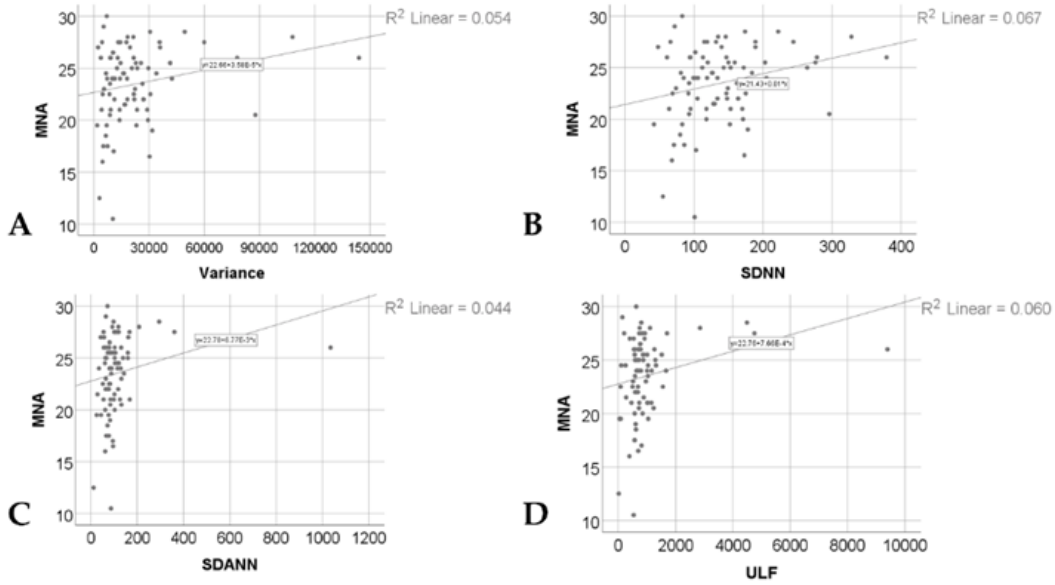

Fig. 1. Correlations between **MNA** and Variance (A), SDNN (B), SDANN (C) and ULF (D).

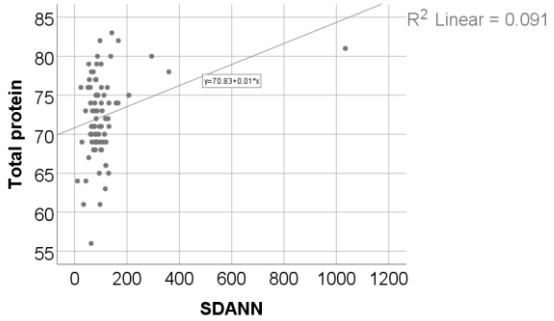

Fig. 2. Correlation between **Total protein value** and **SDANN**

Right arm muscle strength showed significant positive correlations with heart rate variability (Variance, SDNN, SDANN, ULF, VLF, nLF, LF/HF; p between 0.002 and 0.042; ρ between 0.224 and 0.343), reflecting increased cardiovascular autonomic tone. Left arm muscle strength was also significantly correlated with SDANN, ULF, VLF, nLF, and LF/HF (p between 0.005 and 0.041; ρ between 0.225 and 0.304).

Neurocognitive status Assessment

Data analysis showed that 80.7% of patients had no neurocognitive disorder, 12% had mild cognitive impairment, and 7.2% had moderate impairment, according to the MMSE. nLF values were significantly lower in the mild impairment group compared to the unaffected group (p = 0.031),

while differences between the other groups were not significant. GDS scores are associated with lower values of these heart rate variability indicators.

Psycho-Emotional status Assessment

Univariate linear regression models, with the GDS score as the dependent variable, showed significant negative correlations with the Variance parameters (B= 0.000036; 95% CI: -0.000066 - -0.000007; p=0.017), SDNN (B = -0.013657; 95% CI: -0.024875 - -0.002439; p=0.018), ULF (B = -0.000625; 95% CI: -0.001234 - -0.000017; p=0.044) and VLF (B = -0.000202; 95% CI: -0.000403 - -0.000002; p=0.048), indicating that higher (figs. 3, 4).

Urinary incontinence

In this study, the presence of urinary incontinence was significantly associated with lower values of several HRV parameters. Specifically, patients with urinary incontinence showed significantly reduced TINN values (446.12 ± 234.32) compared to those without this condition (575.38 ± 272.12), with a p-value of 0.042. Similarly, Triang-IX values were also lower in the incontinence group (48.64 ± 22.57) *versus* the control group (65.84 ± 29.18), reaching statistical significance (p = 0.010). Frequency domain analysis further indicated that patients with urinary incontinence had significantly lower ULF values (median = 636, IQR = 525-865.5) compared to those without incontinence (median = 771, IQR = 581.7-1030.7), with a p-value of 0.048.

Additionally, normalized high-frequency power (nHF) was also significantly reduced in the incontinence group (median = 43, IQR = 39.2-46) compared to the control group (median = 44.5, IQR = 42.25-48.38), with a p-value of 0.047 (fig. 5).

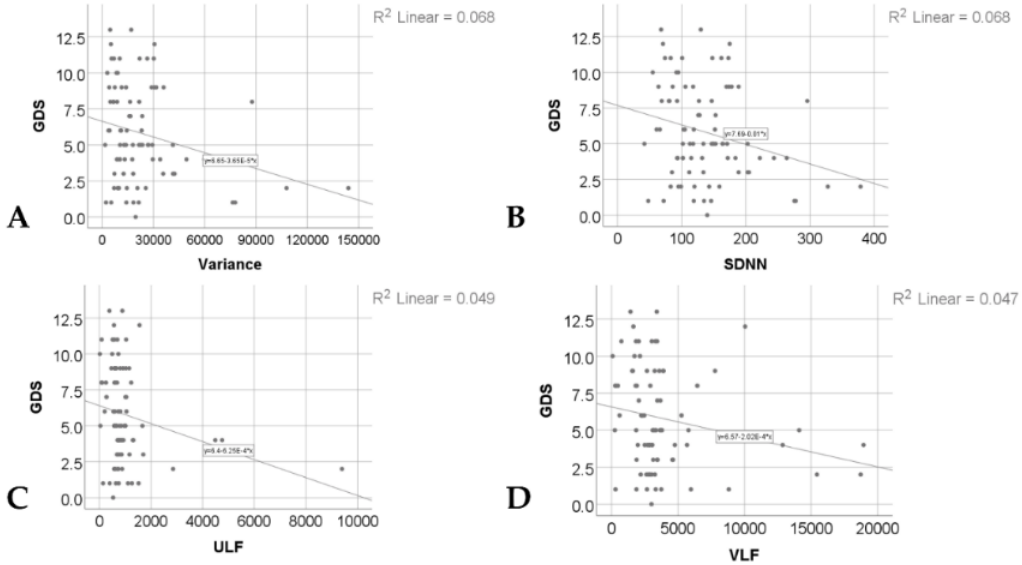

Fig. 3. Correlations between **GDS** and Variance (A), SDNN (B), ULF (C) and VLF (D).

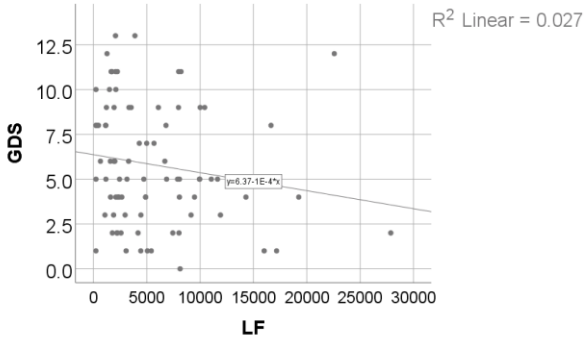

Fig. 4. Correlation between **GDS** and LF.

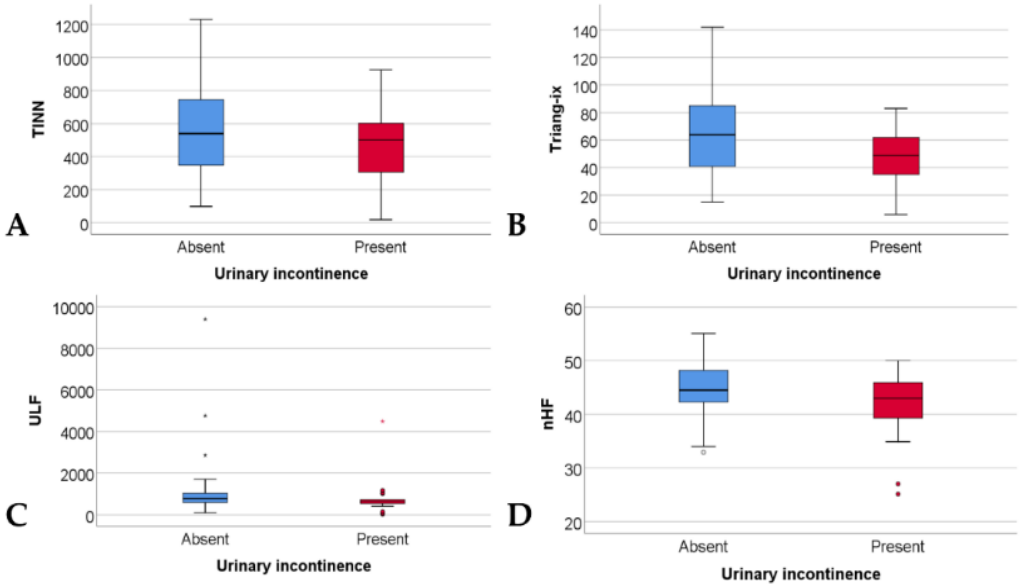

Fig 5. Comparison of TINN (A), Triang-ix (B), ULF (C) and nHF (D) according to the existence of **urinary incontinence**

The results of this study highlight a significant association between the presence of urinary incontinence and decreased HRV, both in the temporal and spectral domains. Patients with urinary incontinence had significantly lower HRV parameters, which may indicate an imbalance in autonomic cardiovascular regulation. These findings suggest that autonomic nervous system dysfunction may play a role in the pathophysiology of urinary incontinence and may represent a potential marker of severity or progression of this condition.

DISCUSSION

The results of our study highlight positive correlations between nutritional status

assessed by the MNA test and heart rate variability parameters (variance, SDNN, SDANN, ULF), which is confirmed by previous studies supporting the hypothesis that good nutritional status is closely linked to better cardiovascular tone (27, 28). The determination of bone mass and body mass index, as an integral part of nutritional status, reflects the link with some HRV parameters as a marker of parasympathetic activity and the autonomic nervous system. Data from the literature support the fact that weight loss in overweight individuals leads to increased parasympathetic activity and increased HRV (11, 13, 14, 15).

Determining muscle strength and the nutritional status (total protein level, hemoglobin, MNA), contributes to a comprehensive assessment in geriatric evaluation and provides information on autonomic function (13, 14, 23).

The results obtained sustain that superior nutritional status is associated with better cardiovascular autonomic activity.

Data on neurocognitive function are partially confirmed by the present study. Patients with mild neurocognitive disorder have lower HRV parameters, concordant with the literature indicating autonomic dysfunction as a biomarker of early cognitive decline. The results obtained are due to the profile of the enrolled patients, who predominantly present with no neurocognitive disorder or mildly impaired neurocognitive function.

Further studies are needed to provide data on involvement in moderate and severe cognitive dysfunction (27).

The lack of significant correlations between HRV parameters and the risk of falling, as assessed by the Downton scale, indicates the need for complementary methods for a more accurate assessment of the risk of falling (28).

Regarding psycho-emotional status, the significant negative correlations between GDS scores and HRV parameters (Variance, SDNN, ULF, VLF) are consistent with multiple studies that have highlighted the link between affective disorders and autonomic nervous system dysfunction (20).

At the same time, this study highlights a significant link between urinary incontinence and decreased heart rate variability, suggesting a possible involvement of autonomic dysfunction in the mechanisms of this condition. The lack of comprehensive studies in the current literature highlights a gap in knowledge, emphasizing the importance of addressing this issue in future clinical practice.

Data on functional status and frailty are currently being analyzed and will be published later as part of intrinsic capacity in old patients.

CONCLUSIONS

This study supports the importance of determining heart rate variability as part of a comprehensive holistic assessment of senior patients.

HRV and its spectral components can be used as biomarkers for early detection and monitoring of the progression of nutritional and psycho-emotional disorders, as well as urinary incontinence in patients over 65 years old.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest, and they received no specific funding regarding this scientific research.

SALIVARY OXIDATIVE STRESS BIOMARKERS AND ORAL HEALTH IN PATIENTS WITH ACTIVE INFLAMMATORY BOWEL DISEASE: PRELIMINARY RESULTS (Abstract): The oral cavity and the intestine are interconnected through shared microbial and immunological pathways, supporting a bidirectional relationship between oral health and inflammatory bowel disease (IBD). Oral pathological conditions are more prevalent and severe in IBD, while oxidative stress represents a key mechanistic link between oral and intestinal inflammation. However, salivary oxidative stress biomarkers remain insufficiently characterized in IBD, and comparative data with healthy controls are limited. **Materials and methods:** This cross-sectional study evaluated adult participants at a single time point, who underwent standardized oral examinations and unstimulated saliva collection. Salivary oxidative stress biomarkers, including superoxide dismutase (SOD), glutathione peroxidase (GPx), malondialdehyde (MDA), and total protein levels, were assessed using validated biochemical methods. Correlation and linear regression analyses were performed to examine associations between salivary biomarkers and clinical dental indices in patients with clinically active IBD, compared with a healthy control group. **Results**: In patients with active IBD, salivary oxidative stress biomarkers (SOD, GPx, MDA) and total protein levels showed weak, non-significant associations with oral health indices. MDA demonstrated modest positive trends with caries experience (DMFT; $r \approx 0.45$) and periodontal status (PDI; $r \approx 0.54$), while SOD and GPx showed minimal correlations across oral parameters (all $p > 0.05$). Compared with controls, patients with IBD showed lower mean salivary SOD and GPx activities and higher MDA levels; however, these intergroup differences did not reach statistical significance. **Conclusions:** Salivary oxidative stress biomarkers were not significantly correlated with dental indices in patients with active IBD. Nevertheless, the observed trends for MDA suggest that lipid peroxidation may more closely reflect the shared chronic inflammatory burden affecting oral and intestinal tissues, warranting further investigation in larger, adequately powered studies. **Keywords:** ORAL HEALTH, PERIODONTAL DISEASE, INFLAMMATORY BOWEL DISEASE, OXIDATIVE STRESS, SALIVARY BIOMARKERS.

INTRODUCTION

The oral cavity and the intestine are distinct yet interconnected components of the orodigestive tract, linked through shared anatomical, microbial, and immunological pathways that generate bidirectional influences on host health. Increasing evidence indicates that oral diseases and inflammatory bowel diseases (IBD) should not be regarded as isolated conditions, but rather as components of a complex and interdependent pathogenic network (1).

Inflammatory bowel diseases, comprising ulcerative colitis and Crohn's disease, are characterized by chronic inflammation of the gastrointestinal tract. Its etiology is multifactorial, involving genetic predisposition, disruption of the intestinal epithelial barrier, and a dysregulated immune response to luminal contents, alongside influences from lifestyle, diet, microbiota composition, and environmental exposures. Certain factors, such as smoking, increase the risk of Crohn's disease, whereas a Western-style diet rich in animal proteins and fats, the frequent use of antibiotics or nonsteroidal anti-inflammatory drugs, and psychosocial stress can trigger or exacerbate IBD (2) (3). Modern dietary patterns, through their profound influence on both the oral and intestinal microbiome, contribute to the increasing susceptibility to IBD and other chronic metabolic disorders (1).

Periodontitis is a chronic inflammatory disease of the tooth-supporting structures, arising from the complex interplay between microbial dysbiosis and the host immune response. This microbial imbalance is characterized by the proliferation of pathogenic oral bacteria and the reduction of protective commensal species, while disease initiation is linked to the accumulation of dental plaque and the subsequent activation of inflammatory pathways that progressively destroy periodontal tissues. In this context, periodontitis is not merely a localized condition but a disorder with significant systemic implications (4).

The relevance of the oral cavity in IBD extends beyond extraintestinal manifestations and reflects a complex interplay between local and systemic inflammatory processes. Crohn's disease may involve oral mucosa, lips, tongue, teeth, and periodontium, with oral involvement reported in approximately 0.5% to 20% of cases (5). Moreover, an increased burden of periodontitis has been documented in patients with IBD compared with the general population, underscoring the bidirectional relationship between these two conditions (6, 7, 8). Additionally, a higher prevalence and severity of periodontitis has been consistently reported among individuals with IBD compared with healthy cohorts, highlighting the influence of intestinal health on the oral cavity (9).

Through the dissemination of oral pathogens and the promotion of low-grade systemic inflammation, periodontitis may contribute to the development or exacerbation of systemic conditions such as IBD, cardiovascular disease, diabetes, and other metabolic or inflammatory complications (10).

The primary aim of our study was to evaluate the relationship between salivary oxidative stress biomarkers, specifically the salivary antioxidant enzymes superoxide dismutase and glutathione peroxidase, as well as malondialdehyde, as a marker of lipid peroxidation, and clinical oral parameters in patients with active IBD, in order to explore their potential relevance as non-invasive indicators of systemic inflammatory burden. A secondary aim was to assess

the associations between these salivary bio markers and established oral health Periodontal Disease Index (PDI) (11), the Simplified Oral Hygiene Index (OHI-S) (12), and the Decayed, Missing, and Filled Teeth (DMFT) (13) with the objective of determining the extent to which salivary oxidative stress reflects oral health status in the context of IBD.

MATERIALS AND METHODS

Patients and study design. A cross-sectional study was conducted, including 30 patients with IBD and a control group of 5 healthy subjects, who were clinically and biologically evaluated at the time of inclusion. Patients with confirmed IBD were recruited from the Institute of Gastroenterology and Hepatology, "Sf. Spiridon" County Clinical Emergency Hospital, Iași. Nineteen patients were diagnosed with ulcerative colitis (UC) and eleven with Crohn's disease (CD). The diagnosis of IBD was established based on clinical, biological, imaging, and endoscopic criteria.

The inclusion criteria comprised adult patients (≥18 years) with a confirmed diagnosis of active IBD (ulcerative colitis or Crohn's disease), without recent major surgical interventions and with no use of antioxidant supplements during the preceding four weeks. The control group included healthy subjects of comparable age, with no systemic inflammatory or autoimmune diseases and a healthy oral status, defined by periodontal indices PDI, oral hygiene OHI-S, and dental caries DMFT within normal ranges, with no evidence of active periodontitis or active carious lesions. The exclusion criteria included patients with diabetes mellitus, advanced cardiovascular or renal diseases, acute oral conditions, recent use of antibiotics or anti-inflammatory drugs, heavy smoking, chronic alcohol consumption, a history of recent dental interventions (<3 months), as well as pregnant or breastfeeding women.

The study protocol was reviewed and approved by the local Ethics Committee, and all procedures were conducted in accordance with the principles of the Declaration of Helsinki. Prior to participation, all subjects received detailed information regarding the study objectives and procedures and provided written informed consent.

Demographic and clinical characteristics were compared between the control group and patients with active IBD. For each participant, age, sex, smoking status, and body mass index (BMI) were recorded. The distribution of categorical variables (sex and active smoking status) was analyzed using Fisher's exact test, while continuous variables (age and BMI) were compared using independent-samples t-tests, with corresponding p-values reported. The study enrolled patients with clinically active IBD, as defined by disease-specific activity scores (Mayo score for UC, Crohn's Disease Activity Index) and elevated inflammatory markers, treated with conventional therapy (5-aminosalicylates and/or immunomodulators) or advanced biologic therapies.

All study patients and subjects underwent oral clinical evaluation as well as biological evaluation of unstimulated saliva samples. Associations between salivary oxidative stress biomarkers (SOD, GPx, MDA, and total proteins) and dental clinical indices were assessed.

Oral Clinical Evaluation. All participants underwent a comprehensive intraoral examination performed by an experienced

dentist. Oral hygiene status was assessed using the Oral Hygiene Index-Simplified (OHI-S), according to standardized methodology. The index was determined by examining six representative dental surfaces (upper right molar, upper left molar, lower right molar, lower left molar, and two central incisors), each evaluated for dental plaque and calculus accumulation. The individual scores were subsequently averaged to obtain the final OHI-S value.

Periodontal status was evaluated using the Periodontal Disease Index (PDI), which includes the examination of the six Ramfjord teeth. For each tooth, gingival inflammation and periodontal attachment loss were assessed, with the final score representing the mean of the recorded values. Higher scores indicate increased periodontal disease severity.

Gingival inflammation was additionally assessed using the Gingival Index (GI), which classifies the severity of gingival inflammation on a scale from 0 (healthy gingiva) to 3 (severe inflammation with bleeding and edema).

Caries experience was evaluated using the DMFT index (Decayed, Missing, Filled Teeth), determined by examining all permanent teeth and recording the number of decayed teeth, teeth missing due to caries, and filled teeth. The total DMFT score reflects cumulative caries experience and overall oral health status.

Biological Evaluation. Following the selection interview and clinical examination, unstimulated saliva samples were collected from all participants included in the study. Unstimulated whole saliva was collected by passive drooling into sterile tubes and transferred using a pipette. Approximately 0.5-1 mL of saliva was collected into sterile Eppendorf tubes. Samples were immediately frozen at -50°C to prevent biomolecule degradation and to avoid repeated freeze-thaw cycles. For biochemical analyses, samples were gradually thawed from -50°C to 4°C, then diluted in cold phosphate-buffered saline (PBS) and homogenized. Superoxide dismutase (SOD) activity was determined using a commercial colorimetric assay kit (SOD Assay Kit, Sigma-Aldrich), based on the competition between xanthine oxidase and SOD for superoxide radical generation. Quantification was performed by measuring absorbance changes at 450 nm. Enzymatic activity was expressed as percentage inhibition of the reaction, according to the manufacturer's instructions.

Glutathione peroxidase (GPx) activity was measured using a commercial enzymatic assay (Glutathione Peroxidase Cellular Activity Assay Kit, Sigma-Aldrich), which quantifies NADPH consumption during the GPx-catalyzed reaction. The decrease in absorbance at 340 nm was recorded kinetically, and GPx activity was calculated in enzymatic units normalized to sample volume and dilution factor.

Malondialdehyde (MDA) concentrations, as a marker of lipid peroxidation, were determined using the thiobarbituric acid (TBA) reaction method, considered a standard approach for quantifying end products of lipid peroxide degradation. The MDA-TBA complexes formed were measured spectrophotometrically at 532 nm, and concentrations were calculated based on a standard calibration curve generated with MDA bis(diethyl acetal). Results were expressed as nmol MDA/mL supernatant.

Total soluble protein levels were determined using the Bradford method with a commercial kit (Rapid Protein Quantification Kit, Sigma-Aldrich). Absorbance was

measured at 595 nm, and protein concentrations were calculated using a bovine serum albumin standard curve. TSP concentrations were used to normalize enzymatic activities (SOD U/mg TSP, GPx U/mL TSP) and, optionally, MDA levels expressed relative to protein content (nmol MDA/mg TSP). Routine hematological and biochemical analyses were performed in patients with active IBD, including C-reactive protein (CRP), fecal calprotectin, fibrinogen, hemoglobin, ferritin, total proteins, and electrolytes. These parameters were interpreted according to the standardized recommendations of the CALM study and were used to confirm disease activity at the time of inclusion.

Statistical Analysis. Clinical and demographic variables are presented as mean ± standard deviation (SD), whereas salivary biomarker data are expressed as mean ± standard error of the mean (SEM).To assess the associations between salivary oxidative stress biomarkers (SOD, GPx, MDA, and total proteins) and dental clinical indices, correlation and regression analyses were performed. For each biomarker-parameter pair, scatter plots were generated to visualize the distribution of individual values. Linear regression models were applied using ordinary least squares (OLS) fitting to estimate the direction and magnitude of the relationships.

The strength of the associations was quantified using Pearson's correlation coefficient (r), while statistical significance was evaluated using two-tailed Pearson correlation tests, with corresponding p-values displayed on each plot. This combined graphical and analytical approach enabled an integrated assessment of both linear trends and the statistical robustness of the observed associations.

RESULTS

Clinical characteristics of study patients and subjects are presented in first table, with no significant differences between groups.

Regarding the specific activity of SOD, a key first-line antioxidant enzyme involved in the defense against oxidative stress development, patients diagnosed with IBD exhibited lower mean SOD activity (0.0207 U/mg protein) compared with the control group (0.0618 U/mg protein) (fig. 1). This difference did not reach statistical significance ($p > 0.05$). The error bars illustrate the within-group variability, indicating a more homogeneous distribution of values among patients and greater dispersion in the control group.

TABLE I.

Clinical characteristics of the control group and patients with IBD

	Controls (n=5)	IBD patients (n = 30)	p- value
Age (years), Mean ± SD	45 ± 5.7	48.8 ± 16.3	0.35
Sex, n (Male/Female)	1/4	20/10	0.14
Active smokers, n (%)	1 (20%)	4 (13.3%)	0.56
BMI, kg/m^2 Mean ± SD	20.26 ± 5.48	23.84 ± 3.04	0.22
Disease duration (years), Mean ± SD	-	7.07 ± 6.77	

BMI: Body-Mass Index

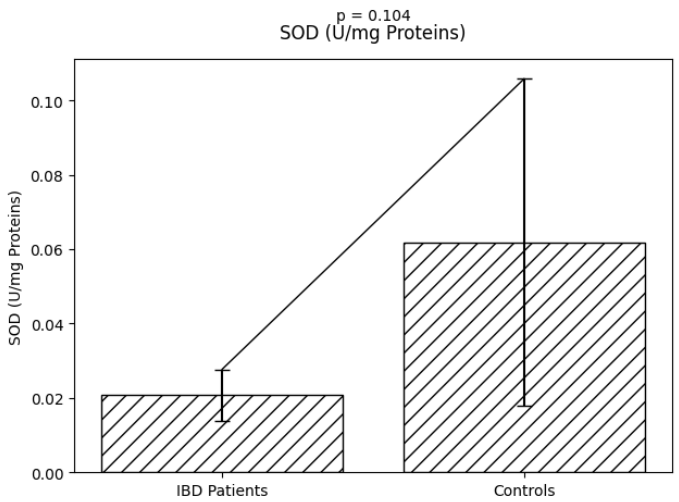

Fig. 1. Specific activity of superoxide dismutase (U/mg protein) in patients with IBD compared with the control group. Values are presented as mean ± SEM.

Regarding the second antioxidant enzyme, the mean GPx activity was 0.2367 ± 0.0044 U/mL in the IBD group, compared with 0.3112 ± 0.0468 U/mL in healthy controls (fig. 2). This difference did not reach statistical significance (p = 0.187). Nevertheless, the observed distribution suggests a tendency toward reduced GPx activity in IBD patients relative to controls, possibly reflecting increased enzymatic consumption under conditions of chronic inflammation and oxidative stress.

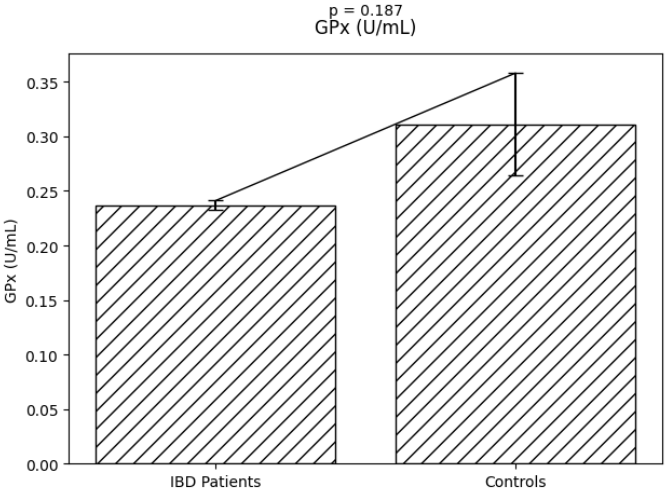

Fig. 2. Glutathione peroxidase (U/mL) activity in patients with IBD compared with the control group. Values are expressed as mean ± SEM. The statistical comparison yielded p = 0.187

Compared to healthy controls, patients with IBD exhibited higher mean salivary MDA concentrations (47.64 ± 3.22 nMol/mL versus 29.43 ± 7.34 nMol/mL) (fig. 3). The error bars reflect within-group variability, showing greater dispersion among controls and a more consistent pattern within the IBD group. A borderline trend toward increased MDA levels in IBD patients relative to controls was observed ($p = 0.066$).

To complement the descriptive analysis of salivary oxidative stress biomarker levels, regression-based graphical evaluations were performed to explore whether these biochemical changes were reflected in oral health status. While the group comparisons illustrated the overall patterns of MDA, SOD, GPx, and total protein concentrations, the scatter plots with linear regression lines provided a detailed view of how these markers aligned with individual dental indices. Together, these two approaches allowed us to assess not only the magnitude of biomarker alterations but also their potential associations with caries experience, periodontal indicators, and cumulative dental disease.

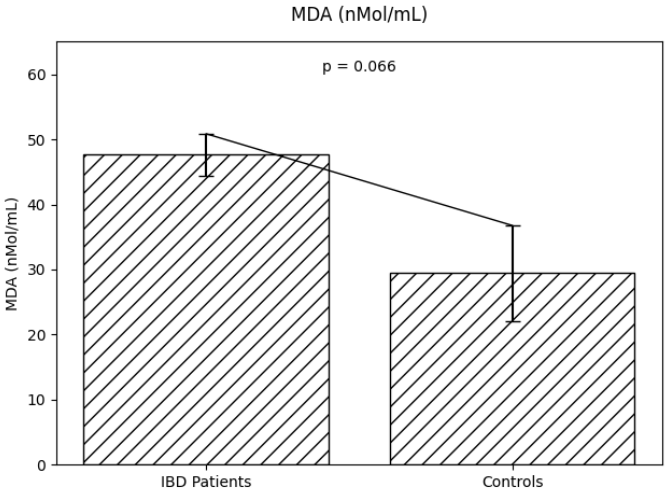

Fig. 3. Mean salivary concentration of MDA (nMol/mL) in patients with IBD compared with the control group. Values are expressed as mean ± SEM. A non-significant trend was observed ($p = 0.066$)

Correlation analysis revealed no statistically significant relationships between SOD activity (fig. 4) and the assessed clinical oral parameters. Only weak positive trends were observed between SOD activity and the filling score ($r = 0.21$; $p = 0.55$) as well as the DMFT index ($r = 0.21$; $p = 0.55$), suggesting that antioxidant activity does not increase proportionally with dental caries severity. The strongest association was identified between SOD activity and the oral hygiene index (OHI-S) ($r = 0.40$; $p = 0.25$); however, this correlation did not reach statistical significance.

Regarding the second antioxidant enzyme, GPx (fig. 5) its activity showed no statistically significant associations with any of the oral clinical parameters evaluat-

ed. Scatterplot analyses revealed only weak and nonsignificant correlations between GPx and the number of cavities, filled teeth, missing teeth, and the overall DMFT index, as well as with PDI and OHI-S. Nevertheless, several upward or downward tendencies could be observed: GPx displayed mild positive associations with cavities (r = 0.26), filled teeth (r = 0.27), DMFT (r = 0.26), and PDI (r = 0.35), suggesting a possible compensatory antioxidant response in individuals with greater caries or periodontal involvement. Conversely, negative trends were noted for missing teeth (r = -0.35) and OHI-S (r = -0.33), indicating that higher tooth loss or poorer oral hygiene may relate to lower GPx activity.

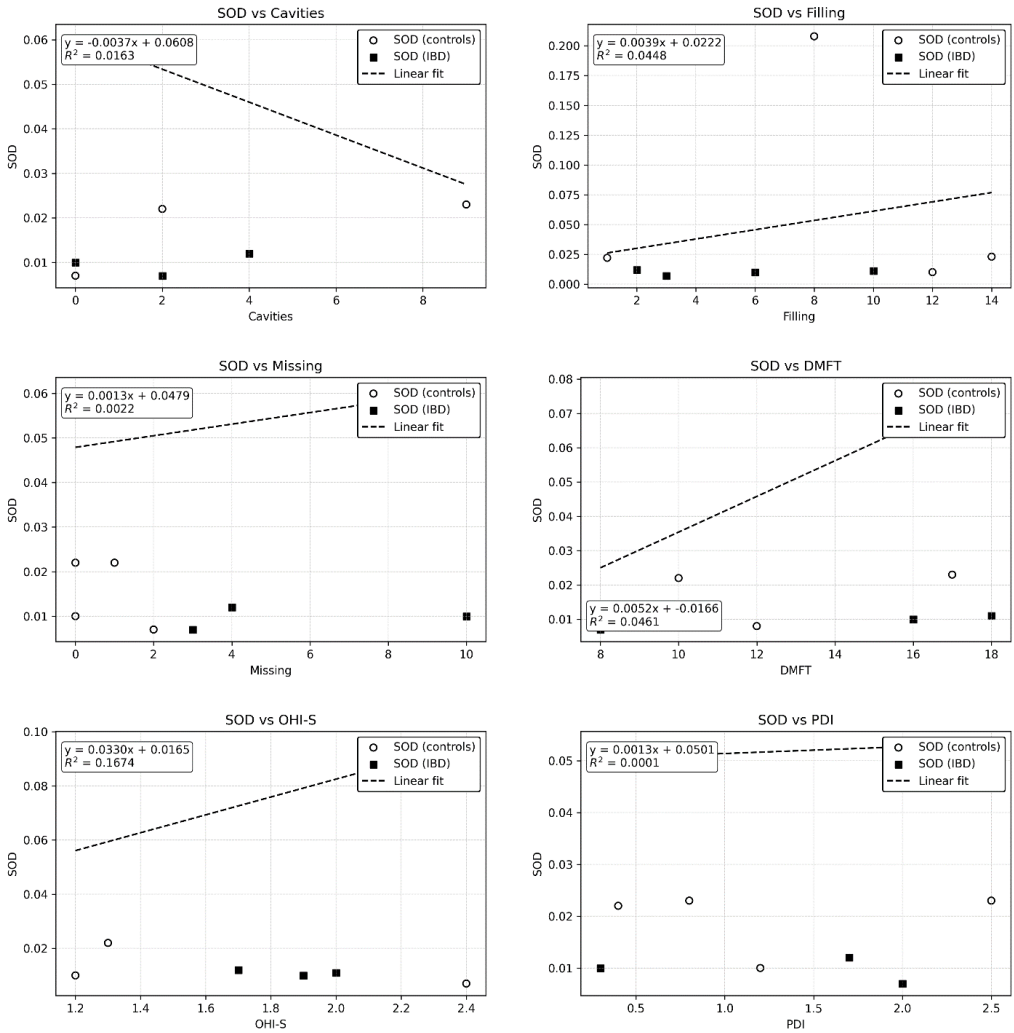

Fig. 4. Scatter plots with linear regression lines illustrating the relationships between salivary SOD and dental clinical indices in controls and patients with IBD.

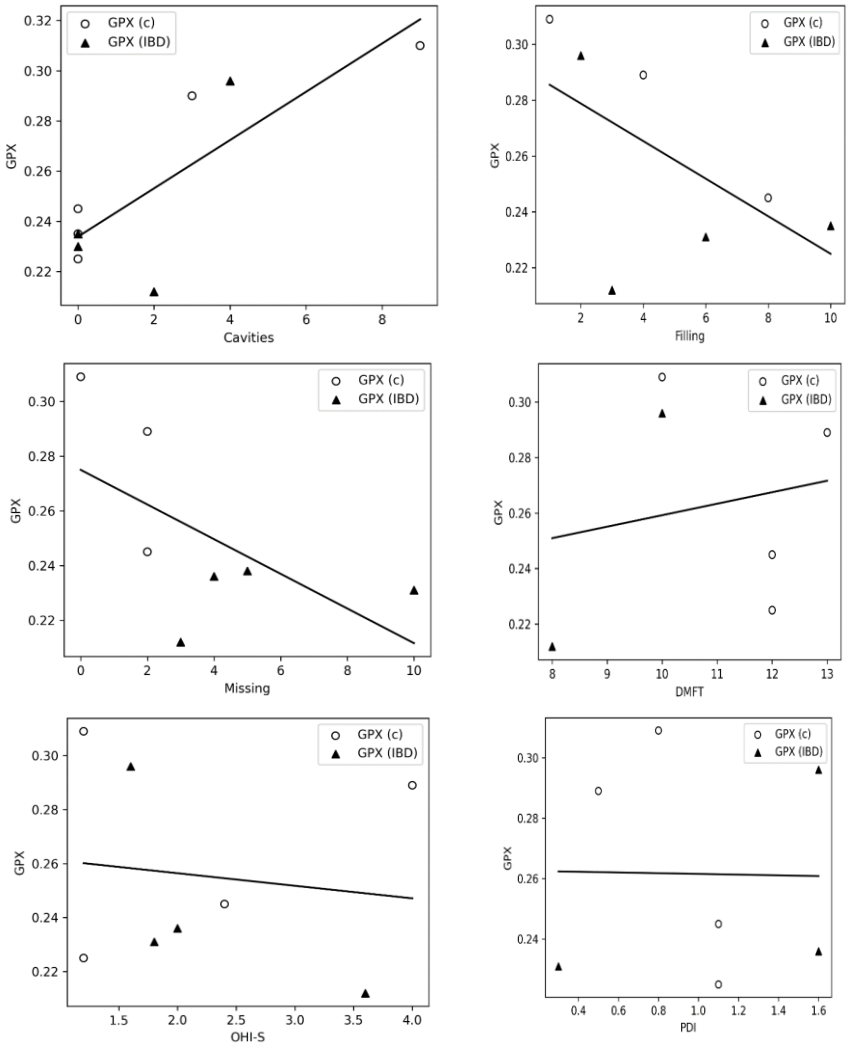

Fig. 5. Scatter plots with regression lines showing the relationship between salivary GPx and dental indices in controls and patients with IBD.

In the case of MDA, an important marker of lipid peroxidation, correlation analyses revealed only weak to moderate, non-significant associations with the evaluated clinical oral parameters (fig. 6). Scatterplot analyses demonstrated a slightly negative trend between MDA levels and the number of carious lesions ($r = -0.37$), suggesting that higher oxidative stress was not accompanied by an increase in active caries within this cohort. In contrast, weak positive correlations were observed with the filling index ($r = 0.38$) and the number of missing teeth ($r = 0.29$), indicating that MDA levels tended to be higher in individuals with a history of dental restorations or tooth loss, although these associations did not reach statistical significance. A moderate positive associa-

tion was also detected with the total DMFT score (r = 0.45) and the periodontal disease index (PDI) (r = 0.54), potentially reflecting a link between cumulative oral disease burden and increased oxidative stress. The weakest relationship was observed with the OHI-S (r = 0.07), suggesting that current oral hygiene status exerted minimal influence on salivary MDA levels. Overall, none of the correlations reached statistical significance; however, several biologically plausible trends point toward a potential cumulative effect of chronic oral pathology on oxidative stress.

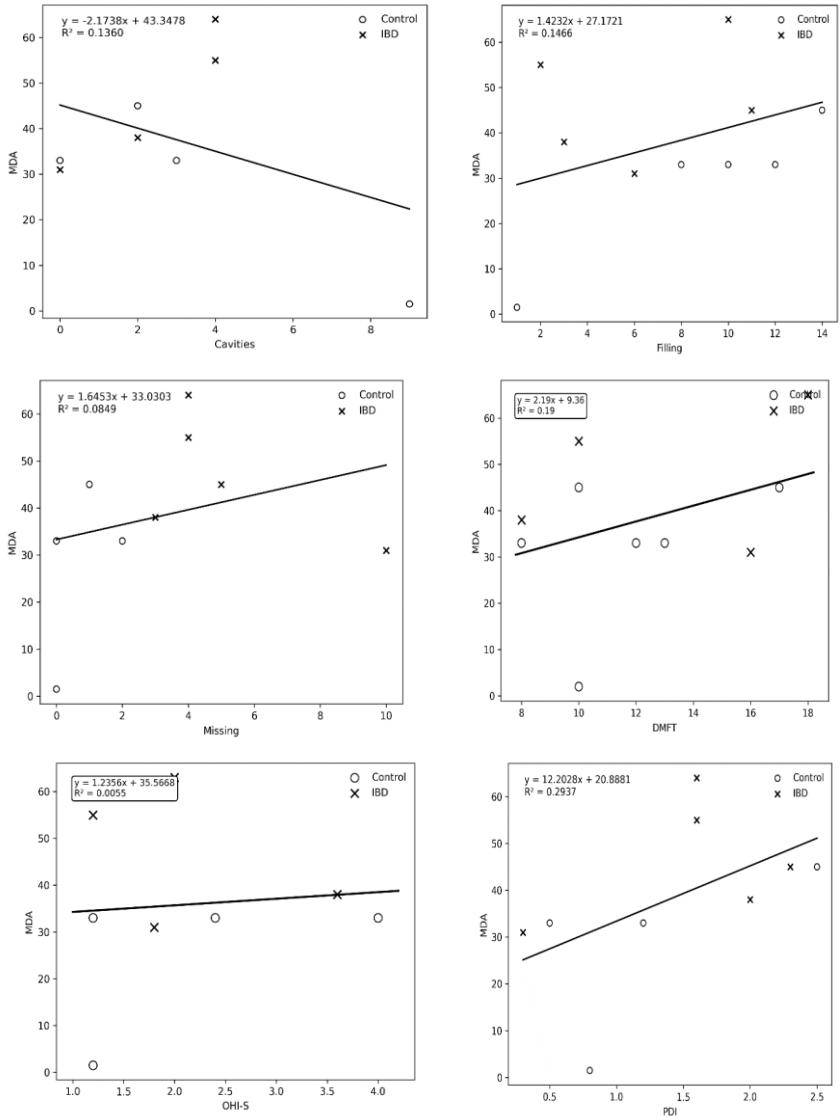

Fig. 6. Scatter plots with linear regression lines illustrating the relationships between salivary MDA and dental clinical indices in controls and patients with IBD

The analysis of total salivary protein levels revealed no statistically significant correlations with the evaluated oral clinical parameters (fig. 7).

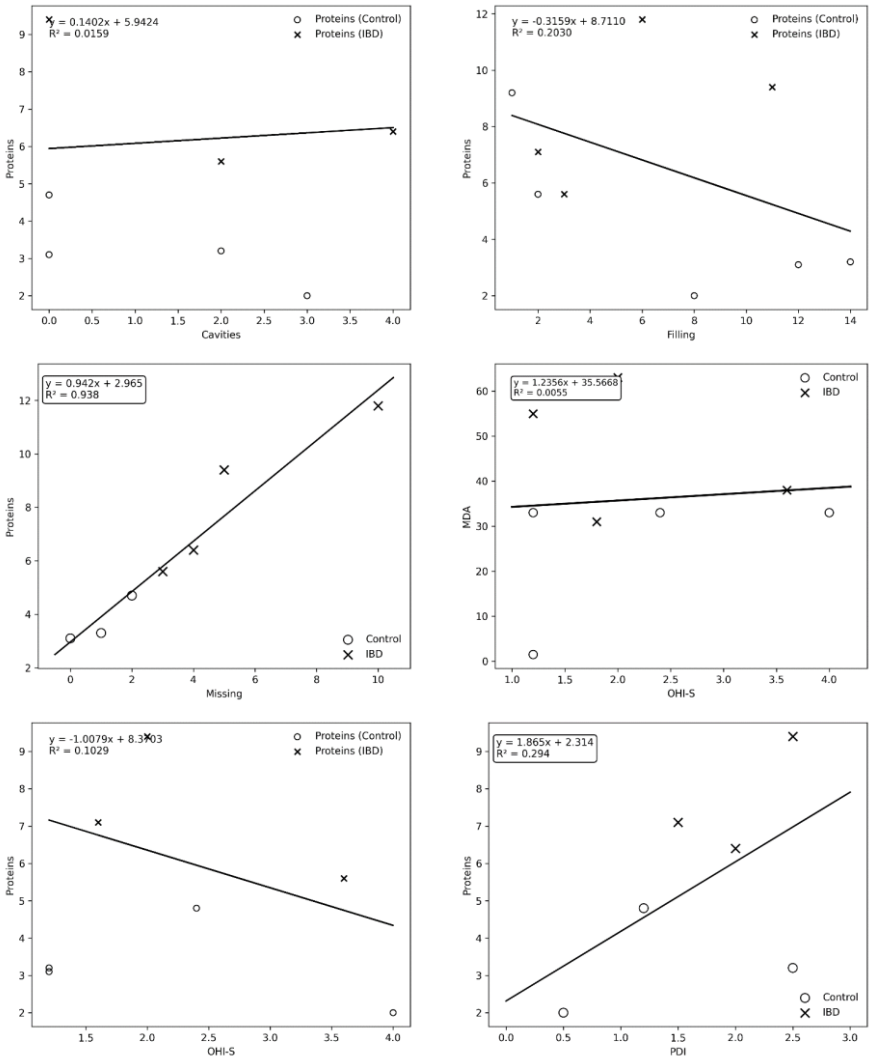

Fig. 7. Scatter plots with linear regression lines illustrating the relationships between salivary protein levels and dental clinical indices in controls and patients with IBD

Scatterplot assessment indicated that protein concentrations exhibited mild positive but nonsignificant trends in relation to the number of filled teeth ($r = 0.18$, $p > 0.05$), missing teeth ($r = 0.22$, $p > 0.05$), and the overall DMFT score ($r = 0.24$, $p > 0.05$), suggesting that individuals with greater cumulative caries experience may present slightly elevated salivary protein levels. In contrast, negative or near-flat associations were observed between protein levels and the number of decayed teeth ($r =$

−0.09, $p > 0.05$), indicating that active carious lesions were not accompanied by increases in salivary protein content. PDI and OHI-S also demonstrated weak and nonsignificant relationships with protein concentrations (PDI: $r = 0.17$, $p > 0.05$; OHI-S: $r = -0.11$, $p > 0.05$), with minimal inter-individual variability. Overall, these findings indicate that salivary protein levels remained relatively stable in both the control and IBD groups, with no significant correlations with caries activity or periodontal status in the present sample.

DISCUSSION

Salivary oxidative stress markers showed biomarker-specific patterns, with MDA levels consistently higher in IBD patients than in controls. Although correlations between MDA and dental indices were weak or borderline significant, their direction suggested an association between greater cumulative dental disease experience and increased lipid peroxidation, with the strongest positive-moderate but nonsignificant-associations observed for DMFT ($r \approx 0.45$) and PDI ($r \approx 0.54$). In contrast, SOD and GPx exhibited low values and minimal variability, resulting in very weak and nonsignificant correlations with clinical oral parameters, indicating limited sensitivity in this small pilot cohort.

In light of our pilot data and previous work from our group, oxidative stress alterations in IBD may reflect not only intestinal inflammation but also associated systemic comorbidities. Our prior studies on chronic inflammatory and hepatobiliary disorders support a broader, multisystem involvement affecting metabolic and oxidative pathways. For example, patients with extrahepatic cholestasis caused by choledocholithiasis were reported to exhibit increased liver stiffness values (6.2-18.4 kPa), which normalized after biliary drainage, with this improvement correlating significantly with reductions in serum bilirubin (14). Furthermore, Trifan *et al*. demonstrated that a 12-week regimen of paritaprevir/ritonavir, ombitasvir and dasabuvir plus ribavirin was safe and achieved nearly 100% sustained virologic response in elderly patients (≥70 years) with HCV genotype 1b compensated cirrhosis (15).

Periodontitis progression has been linked to local oxidative stress, with affected patients showing elevated MDA, hydrogen peroxide, and oxidative DNA damage levels (16). Periodontitis has been associated with reduced SOD and catalase activity and altered oxidative stress biomarkers, including total antioxidant capacity, MDA, and 8-hydroxydeoxyguanosine, compared with healthy controls (17). The pathogenesis of periodontal tissue destruction involves oxidative stress as a central mechanism (16). In a large study, Almerich-Silla *et al*. (17) emphasized that oxidative stress levels in the periodontium are significantly higher in periodontal disease compared with gingivitis or health, displaying a linear trend that parallels disease severity and bleeding on probing (BOP). Patients with periodontitis show increased biomarkers of ROS-mediated tissue damage as well as compensatory increases in antioxidant enzymes within inflamed periodontal tissues and gingival crevicular fluid.

In our study, the MDA-PDI scatterplot showed an upward trend with a steep regression slope, indicating higher MDA levels with increasing periodontal inflammation. Patients with more severe PDI scores exhibited elevated salivary lipid peroxidation, suggesting a relevant association between periodontal severity and oxidative damage. In contrast, GPx and SOD activity showed minimal variation across PDI levels (tab. II), indicating limited antioxidant compensatory responses.

TABLE II.
Summary of the direction and strength of associations between salivary oxidative stress biomarkers and periodontal disease index

Salivary biomarker	Direction of association with PDI	Correlation strength
MDA	Positive (↑)	Moderate
SOD	Very Weak (≈0)	Very Weak
GPx	Weak Positive (↑)	Weak

Regarding dental caries, current evidence indicates that carious lesions are associated with an altered redox response, characterized by increased lipid peroxidation and a reduction in antioxidant capacity during the progression of the disease (18). The direction of these correlations suggests that a greater cumulative dental disease burden may be accompanied by higher salivary lipid peroxidation. Studies on dental caries in children further report that total antioxidant capacity (TAC) decreases in the presence of carious lesions, whereas higher levels of gingival inflammation are paradoxically associated with increased TAC (19). Some studies have reported higher SOD levels in caries-free dentition (18), although these findings remain inconsistent across cohorts. In our study, both SOD and GPx exhibited generally low values and showed very weak correlations with DMFT or the number of carious lesions, suggesting limited sensitivity in detecting oral redox imbalances.

A major limitation of this study is the relatively small sample size, which reduces statistical power and limits the ability to identify robust associations between salivary oxidative stress biomarkers and clinical oral parameters. The substantial biological variability of salivary markers-shaped by disease activity, oral microbiome composition, behavioral factors, and treatment status-may introduce measurement noise that obscures true biological relationships. Particularly relevant is the potential confounding effect of biological therapies used in IBD: anti-TNF agents (infliximab, adalimumab) can suppress systemic inflammation and reactive oxygen species production, potentially lowering MDA levels and increasing antioxidant activity (SOD, GPx). Likewise, IL-12/23 blockade (ustekinumab) and JAK1 inhibition (upadacitinib) may significantly modulate oxidative pathways, while vedolizumab, despite its gut-selective action, may indirectly influence periodontal inflammation through improved intestinal disease control. Consequently, the salivary oxidative stress profile observed in this cohort may reflect both disease-related alterations and treatment-related modulation, making it difficult to attribute changes solely to oral or intestinal pathology. The limited sample size also restricts the generalizability of the findings, underscoring the preliminary nature of these results and the need for larger, longitudinal studies to validate these observations.

CONCLUSIONS

This pilot study suggests that salivary oxidative stress markers, especially MDA, may provide complementary insight into the oral-intestinal inflammatory axis in patients with IBD, although their diagnostic utility appears limited in small, heterogeneous samples. The absence of strong associations for SOD and GPx likely reflects substantial inter-individual variability, disease-related heterogeneity, and the modulatory effects of biological therapies. Larger, longitudinal studies

integrating salivary biomarkers, microbiome profiling, and disease activity indices are required to clarify the role of salivary oxidative stress as a non-invasive marker of systemic and oral inflammation in IBD.

RELATIONSHIP BETWEEN FRACTION OF EXHALED NITRIC OXIDE AND SPIROMETRY PARAMETERS IN ASTHMA (Abstract): **Aim:** Asthma is a chronic airway inflammatory disease with significant social and economic impacts, being associated with a high annual rate of premature deaths. Asthma severity and response to inhaled corticosteroids therapy can be assessed by spirometry parameters and fractional exhaled nitric oxide (FeNO) evaluation. The aim of this study was to evaluate the relationship between spirometry parameters and FeNO values in a group of asthmatic patients. **Materials and methods:** We performed a retrospective analysis on 124 patients with history of asthma of different degrees of severity. All patients have been classified according to the last Global Initiative for Asthma (GINA) criteria and had a complete spirometry and a FeNO measurement. **Results:** The analyzed cases showed a female predominance (62.9%) and a mean patient age of 50.6±16.0 years. A significant association between Forced Expiratory Volume in one second (FEV1) values ($F = 231.167$, $p < 0.001$) or FEV1/FCV ratio ($F = 52.630$, $p < 0.001$) and the degree of asthma control was observed in all patients, regardless of inhaled corticosteroids administration. An inverse correlation between FEV1 and FeNO values ($r = -0.52$, $p < 0.01$) was registered. **Conclusions:** Spirometry parameters and FeNO represent valuable tools in the management of asthma, with higher FeNO values being associated with impaired lung function. **Keywords:** ASTHMA, FEV1, FCV, FeNO.

INTRODUCTION

Asthma is a chronic respiratory disease characterized by wheezing, chest tightness, shortness of breath and cough, with a variable incidence in the population, between 1% and 29%, in different geographical areas (1). According to the latest Global Asthma Report, asthma affects 9.1% of children and 6.6% of the adult population worldwide (2). Due to its continuous increasing incidence in recent decades, asthma is considered a global health problem with impact on the quality of life and is responsible for over 450,000 deaths each year (3). Epidemiological studies on asthma estimate an increase in its incidence in the population worldwide, affecting approximately 520 cases per 100,000 people by 2050 (4).

Mainly produced by epithelial cells, endothelial cells, and neurons in the lung, NO promotes ciliary motility and surfactant secretion, acting also as an airway bronchodilator factor (5-7). However, NO may also be generated by inducible nitric oxide synthase (iNOS) in lung, supporting Th2 lymphocyte differentiation and inhibiting Th1 and Th17 Ly activity in the bronchial mucosa, reflecting its chronic inflammatory status that lead to bronchial epithelial lesions, goblet cell hyperplasia, increased vascular permeability and eosinophilia (6, 7). Thus, NO plays a

dual role, as it can also act as a potent pro-inflammatory factor that supports the airway hyper-responsiveness in T2 asthma (6, 8).

Although the role of NO is still controversial, the evaluation of the fractional exhaled nitric oxide (FeNO) may be an adjunct to diagnostic tools used to assess the type 2 airway inflammation in asthma. Moreover, the addition of FeNO to blood eosinophil counts has been considered as a valuable marker for the assessment eosinophilic bronchial mucosa inflammation in the asthmatic patients (7). Last but not least, FeNO measurement is a non-invasive test with increased compliance in adult and pediatric population, its increased values being correlated with lower lung function, limited response to inhaled corticosteroids, and higher risk for asthma exacerbations (4).

In this context, our study aims to evaluate the association between FeNO values and spirometry parameters in a group of asthmatic patients.

MATERIALS AND METODS

The study group consisted of 124 asthmatic patients undergoing inhaled corticosteroid therapy, diagnosed in the Specialty Ambulatory of the Pneumology Clinic Hospital, Iasi, Romania. Clinical data was anonymously collected from the medical records without active patient participation, in accordance with the principles of the Declaration of Helsinki. Participants were included in the study group based on informed consent and a set of clearly defined inclusion criteria, including age over 18 years, non-smokers (total non-smoker or former occasional smoker), absence of other chronic or acute lung diseases, and the capacity to adequately and correctly perform a spirometry test. The exclusion criteria in the study group were smokers, inability to adequately and correctly perform spirometry tests, and patients with other chronic or acute lung diseases. The FeNO level assessment was performed using the NIOX® device, in accordance with the manufacturer's recommendations. A FeNO value $\geq$ 25 ppb in patients with a medium dose of inhaled corticosteroid therapy and a FeNO value > 20 ppb in patients with a high dose of inhaled corticosteroid therapy were considered pathological according to current guidelines (3). Spirometry test has been performed after FeNO level assessment, by using Vitalograph Alpha Touch after a minimum six-hour withdrawal from a short-acting inhaled beta-agonist, in agreement with the American Thoracic Society recommendations (9). The test was repeated three times and the best spirometry indices values were recorded (9). Forced vital capacity (FVC), forced expiratory volume in one second (FEV1), and FEV1/FVC ratio were registered for each patient. A gender, age and height-wise comparison of spirometry indices was done, being automatically calculated by the device. Airway obstruction was defined as an FEV_1/FVC ratio below the lower normal limit (LLN; Z-score < -1.64).

Statistical analysis has been performed using *SPSS version 25* (IBM, Armonk, NY, USA) and *Microsoft Excel* 2016. Means and standard deviations were computed for continuous variables. Differences in FeNO levels between patient subgroups were analyzed using ANOVA and Pearson correlation tests. A p-value <0.05 was considered as statistically significant.

RESULTS

The predominant female gender was registered in our study group, with 78 cases (62.9%), compared to 46 male cases (37.1%), with a women-to-men ratio of 1.69:1. The most patients were from an urban area (81 of cases; 65.32%) and only 43 patients (34.68%) from the rural area. The mean patients' age was 50.6±16.0 years, showing relatively similar gender ranges, with 51.5±16.4 years in men and 50.1±15.9 years in women. The youngest patient included in the study was 19

years old, while the oldest was 83 years old, and the highest number of cases was observed in the 50-69 age group (28.2%) followed by 60-70 age group (20.2%) (fig. 1).

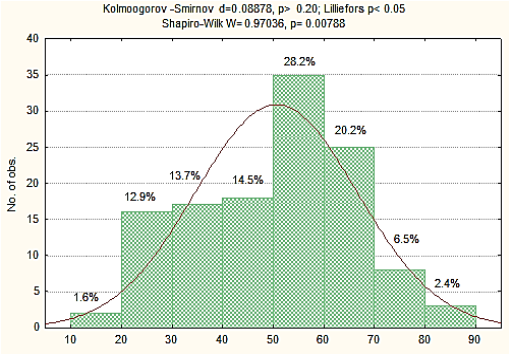

Fig. 1. Age group distribution of the asthmatic patients

Following clinical examination and respiratory exploratory tests, the patients have been included into the following stages: 62 cases (50%) of usual well-controlled (intermittent/mild) asthma, 36 cases (29.03%) of partially controlled (moderate) asthma, and 26 cases (20.97%) of uncontrolled (severe) asthma.

The mean value of FEV1 (% of predicted) for the study group was 78.2%, ranging between 24.1% and 147%, the lowest mean values being registered in the uncontrolled (severe) asthma cases (45.9±9.4), with a minim 24.1% and maximum values of 55.9%. FEV1/FVC ratio had the lowest mean values in uncontrolled asthma patients (55.9±8.0) and the highest values in well-controlled asthma cases (77.6±7.5) (tab. 1). Statistical analysis showed a statistically significant association between asthma severity levels and FEV1 ($F = 231.167$, $p < 0.001$) or between asthma severity and FEV1/FCV ratio ($F = 52.630$, $p < 0.001$).

TABLE I.

Patients' distribution according to FEV1 values (% of predicted) and FEV1/FVC ratio (%) in the study group

Bronchial asthma	FEV1		FEV1/FVC ratio	
	mean ±SD	minimum; maximum	mean ±SD	minimum; maximum
Well-controlled (intermittent/mild)	99.75±10.7	80.3; 147.0	77.6±7.5	59.4; 91.5
Partially controlled (moderate)	68.8±6.3	59.2; 79.8	66.4±7.0	51.2; 78.0
Uncontrolled (severe)	45.9±9.4	24.1; 55.9	55.9±8.0	39.6; 69.2

FEV1 - forced expiratory volume in one second; FVC - forced vital capacity; SD - standard deviation

Asthma duration ranged from 1 to 40 years among the study group patients (Figure 2). The mean asthma duration was 13.1±9.6 years in uncontrolled (severe) asthma, 12.9±11.1 years in partially controlled (moderate) asthma, and 8.25±8.6 years in usual well-controlled (intermittent/mild) asthma.

Most of the asthmatic patients (79 of cases; 63.7%) displayed FeNO values ranging between 20-60 ppb, while 41 patients (33.06%) had FeNO values between 20-40 ppb. A significant FeNO increased value (> 60ppb) has been registered in 31 asthmatic patients (25%) (tab. II).

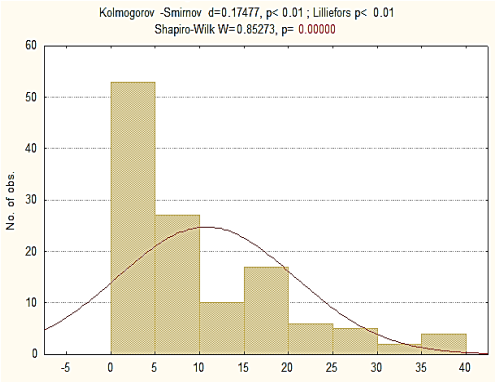

Fig. 2. Distribution of the asthma duration (in years) in the study group

TABLE II.
FeNO values distribution in the study group

	Number of cases	%
0<FENO<=20	14	11.29%
20< FENO <=40	41	33.06%
40< FENO <=60	38	30.65%
60< FENO <=80	11	8.87%
80< FENO <=100	12	9.68%
100< FENO <=120	4	3.23%
120< FENO <=140	4	3.23%
Total	124	

The highest FeNO value in patients with uncontrolled asthma was 126 ppb, while it was only 75 ppb in patients with partially controlled asthma. The lowest FeNO value of 6 ppb was observed in a patient with well-controlled asthma. The mean FeNO value increased progressively with disease severity, being 33.75±17.2 in well-controlled asthma, 43.1±14.9 in partially controlled asthma, and 86.1±22.7 in uncontrolled asthma. Statistical analysis showed a statistically significant association between FeNO levels and asthma severity ($F = 43.905$, $p < 0.001$).

Pearson correlation analysis demonstrated a moderate inverse correlation between FEV1 and FeNO values ($r = -0.52$, $p < 0.01$, 95% CI) (fig. 3).

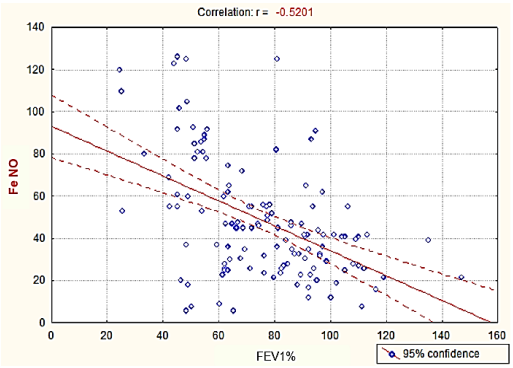

Fig. 3. Scatter plot with regression line showing the correlation between FEV1 and FeNO

DISCUSSION

Although substantial advances have been achieved in the management of bronchial asthma, a significant improvement in patient's quality of life has not been yet demonstrated, despite the implementation of recent standardizations and clinical guideline and the availability of effective therapies (9).

This study was conducted on a group of asthmatic patients diagnosed under background treatment. The study group was predominantly female, a finding that aligns with global epidemiological data, which suggest a higher incidence of asthma in women than in men (9-11). This shift is linked to potentially stronger immune responses in women, smaller airways, and hormonal changes (estrogen and progesterone) affecting airways, leading to more severe symptoms and poorer asthma control in adult women (11). Moreover, estrogens and progesterone were associated with an enhancement of type 2 (T2) airway inflammation by supporting the antigen presentation, Th2 lymphocyte polarization, eosinophils infiltration, and mast cell degranulation (12, 13). Most patients were from urban areas, which may reflect an easier access to medical services and the potential role of the environmental factors (e.g. air pollution), along with unhealthy diet and sedentary life style (11, 14).

GINA emphasizes that asthmatic patients may have a decreased lung ventilation function, expressed by a reduction in FEV1 and FEV1/FVC values. Therefore, spirometry is an important diagnostic tool for asthma management, helping the assessment of the functional status of the patient and guiding the therapy (3). A decrease in FVC and FEV1 values compared to the predicted value was observed in our study, which was significant in patients with partially controlled or uncontrolled asthma. These data are consistent with similar studies that also reported reduced FEV1 and FEV1/FCV values in most asthmatic cases (9, 15). However, low values of these functional parameters could be par-

tially influenced by various factors, such as incorrect inhalation technique, low adherence to treatment, and irregular follow-up visits to medical centers. As a result, additional biomarkers, such as FeNO assessment, may offer supplementary data regarding both diagnosis and disease progression, providing information about the local inflammatory status of the bronchial mucosa (6, 7).

Chronic inflammatory status is a one of the hallmarks of asthma, as in other chronic inflammatory diseases (16-20). According to this criterion, asthma is currently divided into type-2 high, type-2 low, and mixed endotypes (6, 21). Type-2 high asthma is associated with increased eosinophilic airway inflammation and elevated values of inflammatory cytokines (e.g., IL-2, IL-4, IL-5, and IL-13), whereas Type-2 low asthma is characterized by a predominantly neutrophilic inflammation of the bronchial mucosa (6, 22). The mixed asthma includes features of both endotypes (6).

NO secretion in the airway tract may occur *by* enzymatic and non-enzymatic pathways, high FeNO level being correlated with the **T2-high (Type 2) asthma (**6, 22). The NO enzymatic synthesis is controlled by nitric oxide synthases 1-3 (NOS1-3), while NOS-1 and NOS-3 isoforms are constitutively expressed (6). NOS-2 overexpression is induced by pro-inflammatory cytokines (e.g. TNF-α, IL-4, and IL-13), which are intensely produced in **Type 2 asthma** (6). Increased NO levels in asthmatic patients may induce bronchial mucosae hyperemia and edema, bronchial hyper-reactivity, decreased apoptosis of inflammatory cells, and mucus hypersecretion in the bronchial epithelium (7). Therefore, FeNO is considered an adjunct biomarker, reflecting underlying airway inflammation. In this context, an increased concentration of FeNO was detected in asthma patients, including well-controlled ones, compared to normal individuals in different studies (23, 24). These data are consistent with our results, when a mean FeNO value of 33.75±17.2 was identified even in mild forms of asthma, its mean values increasing with asthma severity. Additionally, a meta-analysis performed on a large cohort of asthmatic patients showed that FeNO exhibits higher specificity than sensitivity, which supports its role in the diagnosis of asthma (25). Moreover, the combination of spirometry test results, value of symptom intensity scales, and FeNO measurement increased the asthma diagnostic accuracy with area under curve of 0.76 (95% confidence interval 0.66-0.84) in a group of untreated patients with symptoms suggestive of asthma (26).

However, FeNO evaluation remains an additional tool for asthma diagnosis, high FeNO values increasing the probability of asthma diagnosis, while a negative result does not exclude asthma (3). This is attributable to the fact that FeNO level may be influenced by numerous factors, including time of the day, age, gender or allergen exposure. In this regard, FeNO has a higher value in men than in women, in the afternoon than in the early morning or in patients with other allergic diseases (allergic rhinitis or atopic dermatitis), respectively a lower value in patients who smoke, take inhaled corticosteroids or have a reduced lung function (3, 6). Even so, a FeNO > 20 ppb, added to blood and sputum eosinophils is considered the cut-off for Type 2 inflammation of severe asthma, according to GINA criteria, and it is used to assess this asthma phenotype (3, 6). In addition, a FeNO value > 50 ppb in adults is associated with eosinophilic inflammation in bronchial mucosa, feature that is used to predict the anti-inflammatory therapy response. Furthermore, FeNO value added to lung function parameters is a useful tool to predict the future risk of symptoms exacerbation and loss of asthma control in practice (3, 7, 27). Not least, glucocorticoids are

used to reduce the eosinophilic inflammation in asthmatic patients, therefore FeNO evaluation has a significant role to predict the corticotherapy response of these patients (28). Regarding FeNO and FEV1, a moderate inverse correlation between these two variables has been identified in our study, which is partially consistent with the literature. Thus, a strong correlation between FeNO and FEV1 have been observed in different asthmatic patients (29-32), while other studies have not reported such an association (33, 34). These contradictory results are most likely due to the heterogeneity of the asthma patients' groups studied so far. Despite its limitations, a refractory Type 2 inflammation in asthma is associated with a FeNO > 20 ppb value in patients with high-dose inhaled corticosteroids and itself has been demonstrated to be the strongest predictor of asthma exacerbation in the same patients, compared to periostin and peripheral blood eosinophils count (7, 35). Thus, alongside spirometry, FeNO is a non-invasive method to assess airway inflammation and a significant tool for the asthma therapy management.

CONCLUSIONS

FeNO evaluation is a cost-effective method that is used to detect Type 2 airway inflammation in asthma.

The highest FeNO levels were observed in patients with uncontrolled asthma compared to partially controlled or well-controlled asthma, and these were negatively correlated with FEV1 and FCV values.

Although its value may be influenced by different factors, FeNO may serve as a bio marker for asthma diagnosis, prediction for lung function decline, evaluation of poor asthma control, future symptoms exacerbation risk, and assessment of response to the inhaled corticosteroid therapy in practice.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest, and they received no funding regarding this research.

Z-SCORE: AN INDICATOR OF PROTEIN-CALORIE MALNUTRITION (Abstract). According to the World Health Organization, malnutrition is a chronic disorder of nutritional status, especially among infants and young children, triggered by the imbalance between the nutritional intake and the body's needs to ensure the harmonious growth and development and the fulfillment of the body's specific functions. **Aim:** WHO introduced the Z-score, which has been used for child growth standards; since then, malnutrition and its severity have been determined according to this score. **Material and methods:** We conducted a retrospective study of the cases of malnutrition admitted to the "Pediatric Recovery" department between May and December 2016. The sample considered for the study includes 74 infants showing signs of malnutrition at the moment of hospitalization: significant weight loss, asthenia, fatigue etc. **Results:** Of all the indicators used for the assessment of malnutrition, the Z-score is the most reliable. It expresses the anthropometric value in the number of standard deviations that are inferior or superior to the mean reference value. The graphical processing of the data showed that the Z-score for the height on admission generally ranged from -3.5 to -0.5, being below the reference limit. **Conclusions:** The Z-score is harder to calculate, but it is age-independent and it accurately diagnoses malnutrition. **Keywords:** Z-SCORE, PROTEIN-CALORIE MALNUTRION, DYSTROFIC INFANT.

Half of the nutritional deficiency states occur in the first 6 months of life, overlapping the maximum period of development of the central nervous system, given that the neural multiplication takes place up to 18 months of life. Thus, nutritional deficiency causes severe and often irreversible mental disabilities (1). According to the World Health Organization, malnutrition is a chronic disorder of nutritional status, especially in infants and young children, triggered by the imbalance between the nutritional intake (both caloric and protein intake) and the body's needs to ensure the harmonious growth and development and the fulfillment of the body's specific functions. It is characterized by low birth weight, low weight-for-age and, in chronic forms, by a low weight-for-height (2). In 2006, WHO introduced the Z-score, which has

been used for child growth standards; since then, malnutrition and its severity have been determined according to this score (3). The term protein-calorie malnutrition is used to cover a large number of clinical conditions in adults and children, including: growth failure, marasmus, cachexia, nutritional nanism, kwashiorkor and nutritional edema or hunger edema. Regardless of the clinical differences between these situations, most of the physiological, biochemical and compositional features of the body are common to all forms of severe malnutrition (4).

MATERIAL AND METHODS

We conducted a retrospective study of the cases of malnutrition admitted to the "Pediatric Recovery" department between May and December 2016. The sample considered for the study includes 74 infants showing signs of malnutrition at the moment of hospitalization: significant weight loss, asthenia, fatigue, decreased resistance to cold and infections, dry skin, changes in pigmentation, edema, hypotension and bradycardia, diarrhea and hepatomegaly. The data were taken from the observation sheets of the "Pediatric Recovery" department of the "Sf. Maria" Clinical Emergency Hospital in Iasi, respecting the code of ethics and deontology for scientific research. The study was designed so as to achieve the following objectives: to assess the nutritional status in newborns and infants and to determine the risk factors for malnutrition in newborns and infants in the Iasi area. The observation sheets were used to collect data such as the child's sex, his or her age at the moment of hospitalization, his or her mother's age, the data related to the mother's educational and socioeconomic background, the age of gestation and the child's place of birth as well as the data on his or her condition at birth (Apgar score, weight, height), the way the child was fed before the admission to hospital, the period of hospitalization, the anthropometric indicators on admission and on discharge from hospital and the Z-score calculated for each anthropometric indicator.

RESULTS

Out of the total of 74 infants in the study group (admitted due to malnutrition symptoms), female was found to have a higher incidence (65%) compared to male. The analysis of the statistical data shows that more than half of the mothers were aged less than 25 years old (70%), with a predominance of those under the age of 20, which is correlated with their lack of education. Mothers' marital status was also associated with underweight children for their age. More than half of the mothers in the study are unmarried (66%), and this has a negative influence on the growth and development of children. Most mothers of the children admitted to hospital and considered for this study had more than 4 pregnancies and a low number of abortions, which means they belong to families with many children. This is caused by the mother's lack of education, the low level of living standards and the area where they live – most of them are from rural areas.

The infants included the study group showed symptoms of malnutrition at the moment of admission, although 69% of them were born on term; more than a quarter of them had a birth weight of less than 2500 grams. The birth weight of a child represents an indicator of his / her mother's health and nutritional status and, at the same time, of the population's socioeconomic level. The birth height of the infants included in the study was generally normal, ranging from

47 to 55 cm. This indicator is known to be the most reliable for the infant's age, as it is not influenced by malnutrition in the long term. Most of these infants were hospitalized for one month. The statistical data show that about three quarters of them had an admission weight of less than 5 kg and during the hospitalization they had a weight gain of 500-1,000 grams. The infants' measurement showed that less than half of them had a smaller height than normal and that they gained 1 or 2 cm in height during the month of hospitalization.

Of all the indicators used for the assessment of malnutrition, the Z-score is the most reliable. It expresses the anthropometric value in the number of standard deviations that are inferior or superior to the mean reference value. The graphical processing of the data showed that the Z-score for the height on admission generally ranged from -3.5 to -0.5, being below the reference limit. The normal Z-score must be 0 with ± 1 SD. 4.05% of infants had a Z-score of less than -4.5, 10.81% had a Z-score between -4.5 and -3.5, 16.22% had a Z-score between -3.5 and -2.5, 28.38% had a Z-score between -2.5 and -1.5, 25.68% had Z-score between -1.5 and -0.5, 12.16% had a Z-score between -0.5 and 0.5 and 2.7% had a Z-score above 0.5. The Z-score for the height on discharge was also calculated – its values slightly increased, ranging from -2.5 to -0.5. This showed that the statural deficit decreased; however, the normal values were not reached. The Z-score for the height on discharge indicated that 1.35% of infants had a Z-score below -4.5, 10.81% had a Z-score between -4.5 and 3.5, 10.81% had a Z-score between -3.5 and -2.5, 33.78% had a Z-score between -2.5 and -1.5, 27.03% had a Z-score between -1.5 and -0.5, 14,86% had a Z-score between -0.5 and 0.5 and 1.35% of infants had a Z-score above 0.5.

The indicator weight-for-age was used to calculate the Z-score; along with the processed data, it showed that the nutritional deficiency of the infants included in the study was increased compared to the weight they had on admission. This fact is also confirmed by the literature (7). The analyzed data showed that the Z-score for weight on admission was generally between -5 and -2, which means that the nutritional deficit of these infants was very high. Upon discharge, the Z-score for weight was one standard deviation higher than the normal value – this showed that the care and nutrition during the hospitalization period had the expected effect on the infants in the study group.

Regarding the Z-score for weight on admission, 10.81% of infants had a Z-score of less than -5, 18.92% had a Z-score of -5 to -4, 28.38% had a Z score of -4 and -3, 29.73% had a Z-score between -3 and -2 and 12.16% of infants had a Z-score which above -2. Upon discharge, 4.05% of infants had a Z-score of less than -5, 16.22% of infants had a Z-score of -5 to -4, 25.68% had a Z-score for weight between -4 and -3, 29.73% had a Z-score between -3 and -2, 18.92% had a Z-score between -2 and -1 and 5.41% of infants had a Z-score for weight above -1 (fig. 1). The Z-score for weight-for-height compares the weight of the child under analysis with the weight of a child of the same height in the control population. As for the Z-score for weight-for-height on admission, it appears that 1.35% of infants had a Z-score of less than -5, 14.86% of them had a Z-score ranging from -5 to -4, 24.32% had a Z-score between -4 and -3, 21.62% had a Z-score between -2 and -1, 31.08% had a Z-score

between -1 and 0, 5.41% had a Z-score between 0 and 1 and 1.35% of infants had a Z-score above 1.

On discharge, 1.35% of the infants had a Z-score for weight-for-height which was below -5, 6.76% had a Z-score between -5 and -3, 18.92% had a Z-score between -3 and -2, 24.32% had a Z-score between -2 and -1, 35.14% had a Z-score between -1 and 0, 10.81% had a Z-score between 0 and 1 and 2.70% of infants had a Z-score above 1 (fig. 2).

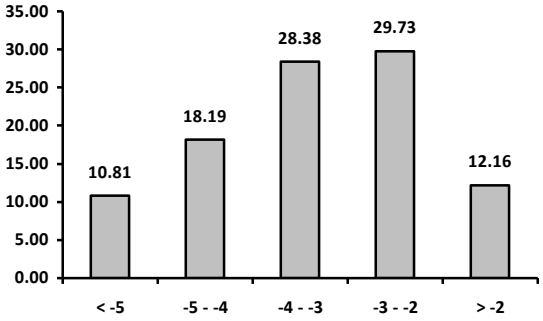

Fig. 1. Z-score for weight on admission

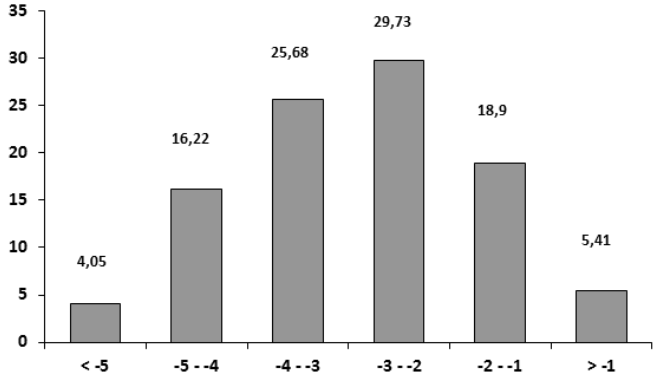

Fig. 2. Z-score for weight on discharge

DISCUSSION

The literature shows that the gender distribution of malnutrition in infants is relatively equal, with a slight predominance of the male gender (7).

In our study, the age distribution shows that more than half of infants were aged less than 3 months old at the moment of their admission to hospital, which corresponds to literature data (5). According to the literature, the ideal age to be a mother is between 25 and 34 years; babies born from mothers under 18 or over 40 years have a higher risk of having health problems (8). The literature shows that the mothers who have a job have higher income and use this income to take care of their children. Therefore, mothers' partici-

pation in generating family income is crucial to improving children's nutritional status (9).

In the current research, mothers gave birth in a maternity unit, most of them in a natural way. The findings of our study are similar with the se from the literature (6).

The scientific literature also shows that, in developing countries, 11% of children have a birth weight below the reference value of 2,500 grams, while in developed countries this percentage is only 2% (10, 11). A study conducted by UNICEF in Romania showed that most cases of low birth weight babies were in Moldavia. Half of the pregnancies were not monitored by medical staff because the access to specialized medical services of the people in the countryside is limited. These data are also confirmed by the literature, which shows that in other parts of the world, more than half of rural mothers do not go to a physician for consultations during pregnancy (3, 4, 6). The literature shows that the prevalence of low weight-for-height is generally below 5%, even in poor countries. In Romania, the percentage is 2.3%, which is the limit between a mild deficit and a moderate deficit; in Moldavia, the prevalence is lower than in the other regions, but this is also due to the smaller size of the children in this region. It has also been found that the environment of origin influences the prevalence of low weight-for-height, which higher in the rural environment (5, 6). Previous studies carried out by UNICEF showed that the low height-for-age in Romania has improved; even if the value of 5% is above the reference value for age groups, it does not exceed the maximum value showing a slight deficit (3, 5, 12).

CONCLUSIONS

In our study, we found that the Z-score is hard to be calculated, but it is age-independent and it accurately diagnoses malnutrition. Malnutrition remains the most common cause of mortality and morbidity among children worldwide. A low socio-economic level means a lack of access to utilities, infrastructure and proper health services, as well as inadequate housing and, most of all, a low-nutrient and vitamin diet. Therefore, the frequency of malnutrition is increased among children from disadvantaged families. Our research shows that with appropriate care and diet children with malnutrition could be recovered.

NEWS

DOSAGE OF REACTIVE C PROTEIN AND TUBERCULOSIS PROPHYLAXIS IN HIV-INFECTED PATIENTS

Prophylaxis of tuberculosis (TB) using isoniazid, in HIV-infected patients (HIVIP) is a challenge because it requires exclusion of the presence of active TB and may increase the risk of isoniazid mono-resistance. The diagnosis of TB is, however, lengthy and costly, which delay the initiation of isoniazid prophylaxis (IP). According to the World Health Organization, the eligibility of HIVIP for IP can be established based on the presence of any one of four predictive symptoms of active TB (current cough, fever, night sweats, weight loss in the past 30 days). This method of clinical triage allows the initiation of IP in less than one third of eligible HIVIP. In this context, it is necessary to use other triage method with greater sensitivity and specificity. Numerous studies have shown that an increase in C-reactive protein (CRP) greater than 10 mg / L is predictive of active TB, regardless of the patient's immune status. A recent study conducted by C. Yoon and collaborators showed that the CRP test can improve active TB screening and eligibility for IP in HIVIP. The study group included 201 patients, of whom 196 HIVIP and 5 HIV-TB co-infection. The results showed that of the 196 HIVIP, 129 patients were eligible for IP using the CRP as screening test, while only 42 patients were eligible for IP on the basis of clinical triage. The results also established that the CRP test had a sensitivity of 80% and a specificity of 87% for the detection of active TB while the clinical triage sensitivity was 100% but with a specificity of 21%. These results have demonstrated the utility of CRP as a quick and inexpensive triage test for establishing eligibility for IP in HIVIP (Yoon C, Davis JL, Huang L, Muzoora C, Byakwaga H, Scibetta C, Bangsberg DR, Nahid P, Semitala FC, Hunt PW, Martin JN, Cattamanchi A. Point-of-care C-reactive protein testing to facilitate implementation of isoniazid preventive therapy for people living with HIV. *J Acquir Immune Defic Syndr* 2017; 65(5): 551-556).

ARTIFICIAL NEURAL NETWORKS - A NEW APPROACH IN NON-INVASIVE MONITORING OF INFLAMMATORY BOWEL DISEASES (Abstract): Our aim was to use artificial neural networks (ANN) for assessing inflammatory bowel disease (IBD) activity using various biological and historical data. **Material and methods**: The study group included 100 patients aged 18-80 years, diagnosed with ulcerative colitis (UC) - 59% and Crohn's Disease (CD) - 41% based on clinical, biological, imaging and histopathological criteria. Both pre-diagnosed and newly diagnosed cases were included. Study database contains multiple parameters obtained through anamnesis, physical exam, evaluation of nutritional status (body mass index), laboratory tests, imaging investigations. We built the neural network using MATLAB 7.0. **Results**: The accuracy of the mathematical model was measured in terms of mean square error (MSE) and mean absolute percentage error (MAPE). Calculated MAPE values for Ulcerative Colitis Disease Activity Index (UCDAI) score and Rachmilewitz score were 52,34% and 47,15% respectively. None of the scores were estimated with excellent or high precision. The Rachmilewitz score was estimated with average accuracy because the network included currently few registered patients. All other scores were estimated with low precision. **Conclusions**: The partial results obtained in the first stage of this study are encouraging given the small number of patients enrolled. Thus, for the next phases of the study, with the ongoing development of the database, we expect to achieve results with higher accuracy. **Keywords**: INFLAMMATORY BOWEL DISEASE, NON-INVASIVE METHODS, ARTIFICIAL NEURAL NETWORKS.

Inflammatory bowel diseases (IBD) include Crohn's disease (CD) and ulcerative colitis (UC). IBD are chronic disorders with recurrent evolution. Complex and inaccurate methods of diagnosis and treatment are conditioned by the unknown etiopathogenesis.

Currently, the techniques used to monitor disease progression are invasive and costly. For this reason, efforts of the scientific community are focused on identifying non-invasive and cost-effective methods capable of accurately assessing disease activity.

Biomarkers are noninvasive or micro invasive, objective, fast and at a lower cost

than other techniques. An ideal biomarker for IBD should be straightforward, cheap, easy to obtain, noninvasive or micro invasive, fast and reproducible. Unfortunately, there is not yet a biomarker that satisfies all these conditions (1, 2, 3, 4, 5).

Recent studies have been published that highlight the utility of artificial neural networks and automatic learning methods in the characterization of various diseases (6, 7, 8, 9). Although the methods are promising, their application in the medical field is still on its way. Therefore, this research area is open to further exploration and can add to the originality of the published works.

The link between biological data, disease history and IBD activity is a complex biological system. Most data have multidimensional and nonlinear links with the severity of the disease. Traditional statistical calculus, such as linear regression models, are too simple to achieve reliable results due to poor statistical stability. Therefore, it is difficult to measure the severity of IBD through traditional statistical models (10). Artificial neural networks are a new computer model inspired from the functioning of human brain. They can build non-linear statistical models to deal with complex biological systems. Artificial neural networks have become a common modeling method in engineering (11). In recent years, artificial neural networks have been successfully introduced for various clinical contexts (10-12). The artificial neural network model has proved to be more accurate and with better performances than multiple logistic regression (13).

In this study, we tried to investigate the possibility of establishing a complex neural correlation between the various biological and historical data of the disease and IBD activity.

MATERIAL AND METHODS

The study group included 100 patients aged 18-80 years, diagnosed with UC (59%) and CD (41%) based on clinical, biological, imaging and histopathological criteria. Both pre-diagnosed and newly diagnosed cases are included in the study.

Exclusion criteria: diagnosis of colorectal cancer; ethanol consumption (≥ 50g/day for men and ≥ 30g/day for women); *Clostridium difficile* infection; neurological, renal, pulmonary, infectious or chronic heart disease

All patients included in the study were interviewed on education, occupational status, smoker status, ethanol consumption.

Laboratory tests. Blood tests include the following: complete blood count with red blood cell count, erythrocyte sedimentation rate (ESR), serum fibrinogen, C reactive protein (CRP), total proteins, protein electrophoresis, sodium (Na), potassium (K), chlorine (Cl), alkaline reserve. These were taken by venous puncture and transmitted to the Hematology and Biochemistry Laboratory of "Sf. Spiridon" County Clinical Emergency Hospital in the context of patient's routine revaluation.

Lower gastrointestinal endoscopy was performed with an Olympus EVIS EXERA II. Investigation was carried out in the context of routine reassessment of patients.

Computed tomography (CT) exam was performed and interpreted by a specialist doctor in the Radiology and Medical Imaging Department of "Sf. Spiridon" County Clinical Emergency Hospital from Iasi.

Study database contains multiple parameters obtained through: anamnesis and disease history considering environmental factors and behaviors (smoker/non-smoker, ethanol consumption, medication, alimentary behavior); physical exam and evalua-

tion of nutritional status (body mass index); laboratory tests; imaging investigations (lower gastrointestinal endoscopy, CT exam).

All personal data is confidential. The database contains patient initials, personal information and study data that can only be accessed by the research team.

Before entering the study, each patient signed an informed consent. Only patients capable of giving their consent were included. Research is not conducted on vulnerable groups.

Artificial neural networks

This research proposes a new approach for addressing the problem of biomarkers in inflammatory bowel diseases. Thus, an interdisciplinary method has been implemented: artificial neural networks. These systems are known in literature as "learning" systems. They can be trained with a set of well-known data (patients already evaluated) and then interrogated for new cases.

An artificial neural network can mimic a biological neural system, both structurally and functionally. The network contains an input layer, an output layer and one or more hidden layers. It is made up of a set of complex processing units (neurons) interconnected by weighted links (analogy to synapses in the nervous system). Units (neurons) receive information from other neurons. If a threshold is reached, the neuron sends information to the other connected neurons; otherwise it does not send anything. In the learning phase, data with results already known are introduced into the system and the interneuronal connection weights are updated according to a training algorithm. Training process ends when the total system error is minimal. A trained neural network extracts its calculation rules from the matrix of weights between neurons. This allows to predict the outcome of new cases that have never been introduced into the system (14, 15, 16).

In this study, we built the neural network using Matlab 7.0.

Active parameters for the input layer (i.e. those with the highest estimation power), were determined using statistical methods (t-student and chi² tests). Statistical significance was set to $p = 0.05$.

Therefore, input layer contains 25 neurons that are:

- *clinical:* smoker status; disease duration; number of kilograms lost in the last three months; presence of asthenia; clinical data from the scores used in the output layer (UCDAI, Rachmilewitz etc.)

- *biological:* white blood cells count (WBC); hemoglobin (HGB); hematocrit (HCT); platelet count (PLT); red cell distribution weight (RDW); ESR; fibrinogen; cholesterol; iron; ferritin; CRP; protein electrophoresis.

The output layer consists of the following scores: Ulcerative Colitis Disease Activity Index (UCDAI); Rachmilewitz; Ulcerative Colitis Endoscopic Index of Severity (UCEIS); Geboes (histological score); Crohn's Disease Endoscopic Index of Severity (CDEIS); Simple Endoscopic Score for Crohn's Disease (SES-CD).

Hidden layers were used to allow the development of complex relationships between input and output neurons. Hyperbolic tangent transfer functions were used in the hidden and output layer. Each variable was normalized in the range (0, 1).

80 patients were assigned to the training cohort and 20 patients were assigned to the validation cohort.

The number of hidden layers and the number of neurons within hidden layers

were determined by a trial and error process. After repeated attempts, a four-layer network with ten neurons in each hidden layer was considered the best mathematical model.

RESULTS

A descriptive statistic for a part of the data in the input layer is shown below, describing separately the training cohort and the validation cohort (tab. I).

TABLE I

Descriptive statistics

	Training cohort			Validation cohort		
	Min	Max	Mean + SD	Min	Max	Mean + SD
WBC	2,86	15,12	10,1 +/- 3,1	3,63	13,85	9,88 +/-4,7
PLT	132	550	390,2 +/- 6,5	144	470	363,3 +/- 10,1
RDW	29	62	44,9 +/- 4,7	32	58	40,3 +/- 5,2
ESR 1h	1	35	13,5 +/- 4,2	3	27	12,7 +/- 5,8
CRP	0,1	31,6	8,3 +/- 6,8	0,12	35,8	10,1 +/- 6,5

The accuracy of the mathematical model is measured in terms of mean square error (MSE) and mean absolute percentage error (MAPE). MSE is calculated based on the desired and estimated value and then the average for all data is determined. It is used as a good fit indicator of the model. MAPE indicates the mean deviation from the desired value and is usually expressed as a percentage. The precision of a model is considered excellent if MAPE value is less than 10%.

MAPE value from 10 to 20%, from 20 to 50% and above 50% is high, medium and low accuracy (17).

The formulas of MSE and MAPE are presented below:

$$MSE = \frac{1}{n}\sum_{i=1}^{n}\left(Y_i - Y_{i'}\right)^2$$

$$MAPE = \frac{1}{n}\sum_{i=1}^{n}\frac{\left|Y_i - Y_{i'}\right|}{Y_i} \times 100\%$$

where n represents the number of inputs, Y_i is the desired value for the ith input, $Y_{i'}$ is the calculated value for the ith input.

The calculated MSE and MAPE values for the output layer scores are (tab. II):

TABLE II

Calculated MSE and MAPE values

	MSE	MAPE
UCDAI	0,092	52,34%
Rachmilewitz	0,065	47,15%
UCEIS	0,212	65,37%
GEBOES	0,342	70,23%
CDEIS	0,156	62,48%
SES-CD	0,301	69,52%

None of the scores were estimated with excellent or high precision. The Rachmilewitz score was estimated with average accuracy, although with a value close to the medium range upper limit.

The lack of significant results is because the network included currently few registered patients. Neural networks need hundreds, up to thousands of records to deliver significant results.

In this context, it is encouraging that Rachmilewitz score was estimated with an average accuracy. Thus, the main direction for the next phase of the study is to populate the database with as many patients as possible. This will improve accuracy of the results.

Romania is a country with limited re-

sources and restricted access to expensive medical investigations. Finding an artificial neural network system capable of non-invasively evaluating inflammatory bowel disease activity, will reduce the number and cost of invasive endoscopic and histo-pathological investigations.

CONCLUSIONS

The partial results obtained in the first stage of this study are encouraging, given the small number of patients enrolled. Thus, for the next phases of the study, with the ongoing development of the database, we expect to achieve results with higher accuracy.

EVALUATION OF AGREEMENT BETWEEN FUNGAL CULTURE AND PCR FOR DIAGNOSIS OF ONYCHOMYCOSIS

Fungal culture for diagnosis of onychomycosis has the disadvantage of being time consuming and less sensitive. PCR techniques are faster and may be more suited for diagnosing nondermatophyte mold infections. In a study by Gupta *et al*, PCR methods were compare to fungal culture to measure their agreement for detection of microorganisms causing onychomycosis. For this purpose, single samples from 167 patients with suspected onychomycosis and repeated serial samples from 43 patients were analyzed using both methods to detect 16 dermatophyte species and 5 nondermatophyte molds. Kappa statistic (κ) was used to measure the agreement between methods. Regarding the identification of all infecting organisms, the two methods showed a good agreement ($\kappa = 0.32$ for single samples and $\kappa = 0.38$ for repeated samples respectively). In the case of dermatophytes, the agreement was moderate ($\kappa = 0.44$ for single samples and $\kappa = 0.42$ for repeated samples respectively). In the case of nondermatophyte molds there was a poor agreement for single samples ($\kappa = 0.16$) but a good agreement for repeated samples ($\kappa = 0.25$). The study concluded that there was a three to four times higher risk of a false-negative result when using fungal culture compared with PCR. The authors also recommend the use of serial samples, since repeated sampling increases the agreement of nondermatophyte mold identification. (Gupta AK, Nakrieko KA.Onychomycosis Infections. PSYCHOLOGICAL PROBLEMS RELATED TO HEPATITIS C IN PEDIATRIC PATIENTS AFTER ONE YEAR OF TREATMENT (Abstract). The treatment of hepatitis C in pediatric patients determines physical and psychological effects. **Aim**: to identify psychological problems in children infected with HCV. **Material and methods**: a number of 32 children (20 boys and 12 girls) with no psychiatric problems were evaluated after one year of treatment for hepatitis C. Variables like age, gender and the presence of asthenia, irritability, agitation, sadness, somnolence, fatigability, insomnia and behavioral problems were considered. Data were recorded in the medical paper, as results of self-evaluation and aspects declared by the parents. Statistical data were processed using SPSS 17.00. **Results:** A number of 6 patients (18.75%) presented insomnia. Fatigability was recorded in 96.88% of questioned patients and somnolence was identified in 25% of them. A number of 30 patients (93.75%) claimed that they felt sad at the time of the evaluation. Significant statistical correlations were identified between some variables. **Conclusions**: Results are important to prove the necessity of psychological care during the treatment for hepatitis C, for both patients and parents. **Keywords**: HEPATITIS C, CHILDREN, FATIGABILITY, SADNESS, BEHAVIORAL PROBLEMS.

Hepatitis C is a liver disease caused by the hepatitis C virus: the virus can cause both acute and chronic hepatitis, ranging in severity from a mild illness lasting a few weeks to a serious, lifelong illness. Globally, *World Health Organization* (WHO) statistics estimate that 71 million people have chronic hepatitis C infection. Hepatitis C virus (HCV) causes both acute and chronic infection. Acute HCV infection is usually asymptomatic, and is only very rarely (if ever) associated with a life-threatening disease. About 15-45% of infected persons spontaneously clear the virus within 6 months of infection without any treatment (1).

Eastern Mediterranean and European regions are the most affected, with a prevalence of 2.3% and 1.5%, respectively. According to WHO statistics, the prevalence of HCV infection in other WHO regions varies from 0.5% to 1.0% and can be concentrated in certain populations (for example, among people who inject drugs) and/or in general populations. There are multiple strains (or genotypes) of the HCV virus and their distribution varies by region (1). According to the *Centers for Disease Control*

and Prevention, a prevalence of 2% or greater is defined as regions/countries with high risks of HBV infections. Regions from sub-Saharan Africa, from Central and Southeast Asia, and China are considered very high-risk regions (2).

Apart from geographical area criteria, other criteria are related to high rates of HCV: HIV-positive patients, injection drug users, home living with infected family members, and sexual relationship between men. The recommendation of screening for HCV also refers to groups like chronic kidney disease patients under hemodialysis or patients under immunosuppressive therapy. Also, some recommendations refer to inmates, persons exposed to infected blood or fluids, persons with elevated risk behaviors, in the case of blood transfusion or organ donors. For these high risk categories, the *American Association for the Study of Liver Diseases* recommends the screening for HCV. The combination of factors mentioned above determines a more focused attention and more intensive counselling for screening. According to scientific studies, in the USA, being a man, black and aged about 30-39 are characteristics of infected persons (3).

Risk of chronic HCV is inversely correlated with age (90% of infants, 25% to 50% of children aged 1 to 5 years, under 5% of older children and adults (4). Regarding hepatitis C, it seems that there are 10 times more people living with HCV than HIV (Joint United Nations Programme on HIV/AIDS (5).

There is a need for studies targeting HCV children and adolescents' psychological aspects and the effect of treatment on quality of life. Few studies included children and several studies used a broad range (e.g. age cohort 0-20) to describe prevalence in younger populations. A literature review targeting HCV infection among children identified that the highest rate is in low-income countries and the lowest, in high-income countries (6). HCV affects 0, 2-2% of the general population under 18 years old. Some statistical data prove 6600 cases in Canada (7) and 23.000-46.000 cases in USA (8).

In Romania, the prevalence of HCV infection is about 3.23%, significant differences being recorded between geographical regions: Moldova (4.25%), Muntenia and Dobrogea (3.35%), respectively, Transilvania and Banat with 2.63%. (9). Another study focusing on 17 counties proves a prevalence of 4.6%, with different scores for Bucureşti (3.05%), Craiova (3.27%) and a high rate of prevalence in south-eastern Romania (6.37%) (10).

The aim of the study is to identify psychological problems in children infected with HCV, after one year of treatment.

MATERIAL AND METHODS

A number of 32 children (20 boys and 12 girls) registered with the diagnostic of hepatitis C in "Sf. Maria" Hospital for Children, Iasi, Romania, were evaluated in terms of psychological and behavioral aspects, one year after the beginning of their treatment with interferon, between 2012-2015, in a children's hospital in north-eastern Romania. None of them was identified as suffering from a psychiatric disease.

The variables taken into consideration were: age, gender, the presence of asthenia, irritability, agitation, sadness, somnolence, fatigability, insomnia and behavioral problems.

Data were recorded in the medical paper, after clinical investigation (observational evaluation, self-evaluation and parents' evaluation). Statistical data were processed using the software *SPSS 17.00*.

RESULTS

The age mean is 12.03 ± 3.81, with a minimum of 6 years old and a maximum of 18 (the average for boys is 11.75 ± 3.93 and 12.50 ± 3.77 for girls). All children are enrolled in schools and 59.38% of them live in urban areas. They come from 8 counties in north-eastern Romania: Iași (53.13%), Suceava (6.25%), Galați (6.25%), Botoșani (9.38%), Vaslui (15.63%), Neamț (3.13%), București (3.13%) and Bacău (3.13%).

The distribution of subjects according to the age at which they started their treatment is presented in Table I.

Behavioral problems were identified neither in girls, nor in boys.

Insomnia was also registered, 6 patients (18.75% of the questioned subjects) claimed that they had sleep-related problems - 5 boys (age of 9, 10, 15 and 2 boys of 18 years old) and one girl aged 18. Four out of 6 patients identified with insomnia are older than 15 and have a college education.

Fatigability was registered in 31 cases (96.88%) and somnolence was identified in 8 patients (25%), 6 boys and one girl. The presence of somnolence by gender is presented in Figure 1.

TABLE I.

The distribution of children considering their age at the beginning of the treatment

Age	6	7	8	9	10	11	12	13	14	15	16	17	18
N	4	1	2	4	2	3	3	1	2	4	1	4	1
%	12.50	3.13	6.25	12.50	6.25	9.38	9.38	3.13	6.25	12.50	3.13	12.50	3.13

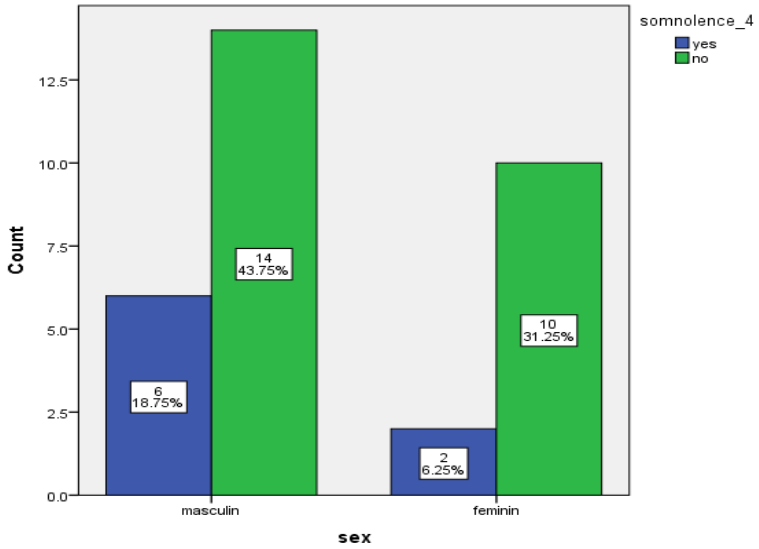

Fig. 1. The frequency of insomnia considering the gender of the patients

A number of 30 patients (93.75%) claimed that they felt sad at the time of the evaluation.

In the case of 10 children (31.25%) agitation was identified. The distribution according to the age and gender is presented in Figure 2. Only 4 of all evaluated patients (12.50%) presented irritability.

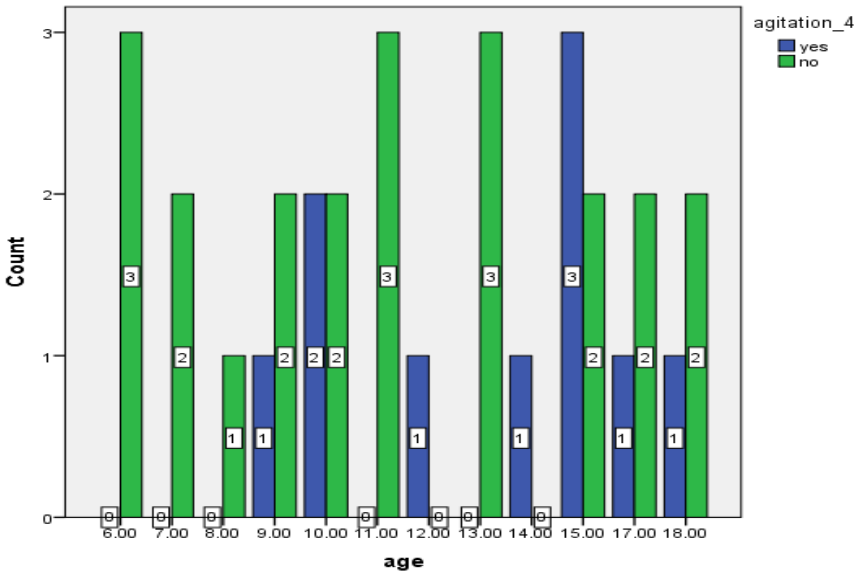

Fig. 2. The distribution of variable agitation considering age and gender

DISCUSSION

The correlational analysis proved that there is a positive relationship between variables:

- age and somnolence (.464**, p = .007),
- irritability and agitation (.357*, p = .045)
- irritability and insomnia (.545**, p = .001).

A significant negative correlation was identified between agitation and somnolence (-389*, p = .028), meaning that the more agitated the person is, the less somnolence is present.

The results could be explained by the fact that the older the patients are, the more scholastic and extra-school activity they are involved in.

The more irritability they feel, the more frequent the presence of sleep related-problems and agitation is.

Treatment and its effects on the psychological well-being of the pediatric patient

For the children, any opportunity should be taken to intervene earlier and potentially clear the infection and halt the progression of disease before there is significant impact on quality of life. A few studies point to psychological problems because of HCV treatment.

Depression. Teenagers using injected drugs run high risks of being infected with HCV. In most of the cases, depression and drug addiction are correlated: depressed people try to cope with the disease looking for drugs' effect. Consequently, this population becomes more vulnerable to psychiatric disorders during HCV treatment. The treatment of psychiatric disorders among drug users is a must. Regarding the management of HCV infection, the National Institute of Health recommends the diagnosis and treatment of depressive problems before the start of HCV treatment. The rates for depressive disorders among injecting drug

users are higher compared to other patients suffering from HCV, some researches identifying rates among adults of about 56% to 75% (11, 12, 13). The use of interferon increases psychiatric disorders; therefore, for patients already suffering from one, the risk of major depression is very high.

Cognitive deficit. In adults, HCV is associated with a low level of quality of life and cognitive impairments. In children, less scientific data are available, compared to adult patients. Data show that there are some cognitive dysfunctions. In its early stage, HCV treatment does not have important negative effects on QoL or on cognitive, behavioral or emotional levels. At older ages, emotional, cognitive and behavioral impairments diminish after the treatment is finished. A study of Rodrigue et al. found that symptoms of stress, depression, and anxiety are not pervasive in infected children and adolescents (14). The researchers proved that almost 20% of HCV-infected children had executive function impairments, preventing them from planning, organizing, and inhibiting their own behaviors. Children with HCV do not present a global impairment in quality of life, or in cognitive, behavioral, or emotional functioning, but children with HCV infection have worse cognitive functioning than the normal comparative group.

Self-esteem. Researches on the impact of hepatitis C on the level of self-esteem are poorly represented in the scientific literature. Studies prove that the internalized stigma is associated with low levels of self–esteem (15).

Family members' and caregivers' support for the quality of life of HCV pediatric patients.

The information regarding quality of life, psycho-behavioral changes or cognitive and emotional impairments during interferon treatment in children should be evaluated considering age and the relationship with parents (since, during adolescence, parent-child relationships could worsen and the tremendous changes during this stage of life could be exaggerated by parents). Teachers and caregivers should be warned about these changes and both must take into consideration the interferon effects, especially when the treatment is initiated, and should offer support. Also, teenagers should be carefully supervised considering the possibility to have risky behaviors: sharing razors for boys, nail files for girls, or the risk of drug consumption.

A research of Iorio et al. (16) identified in children that during the treatment for HCV with interferon irritability increased and the quality of life decreased. Also, some other psychosocial problems were identified by Nydegger et al. (17), proving that significantly lower physical and mental QoL is identified for children who acquired HCV in the first year of life.

In the case of children, the vertical transmission has an impact on parents' psychological well-being. Approximately 60% of children are infected this way. If the virus is transmitted by the mother, she will feel guilty. All caregivers of HCV-infected children reported higher stress and concern over their child's health, believing that it would deteriorate, and reported that HCV infection had a negative impact on the overall functioning of the family (18). In this situation, family support is very important for the quality of life of the patient and parents (especially mothers).

CONCLUSIONS

Managing psychological aspects during treatment for hepatitis C must be one of the

goals of the healthcare strategy for children and adolescents.

Almost all patients accused sadness and fatigability and the high rates imposed close psychological assistance.

A quarter of them, especially adolescents, accused somnolence.

A psychosocial intervention must be taken into consideration for all patients under treatment with interferon for 12 months and to train parents how to offer support to their children.

OSTEOGENESIS IMPERFECTA-ACQUISITION OF BONE MASS AND GROWTH UNDER BISPHOSPHONATE AND rhGH-TREATMENT. PERSONAL EXPERIENCE (Abstract) **Aim**: To verify the efficacy of bisphosphonates (Bis) in combination with recombinant human GH (rhGH) in children with osteogenesis imperfecta (OI). We also aimed at demonstrating a possible improvement in bone mineral density (BMD) and growth velocity when combined treatment of Bis and rhGH is used. **Material and methods:** Retrospective observational study on eight children with OI type IA. The treatment consisted in the administration of Risedronate for 24 months. The children weighing under 30 kg received 35 mg Risedronate/14 days. The children weighing over 30 kg received 35mg Risedronate / weekly. Lumbar spine and whole body bone mineral density (BMD) were assessed at baseline and after 24 months. The DXA-BMD results were compared with the reference data for bone density; in all cases the score at baseline was higher than -2.5. Two of the children with significant growth disorders and in which over the past year growth velocity was less than 2 cm/year, were also treated with rhGH at a dosage of 0.3 mg kg/week. **Results and discussion:** An increase in lumbar spine and whole body BMD was recorded both in girls and boys after two years of Bis therapy. After the study ended, the children have continued their treatment with Bis. The combined treatment resulted in improved linear growth. **Conclusions:** Our experience suggests that the use of combined therapy of growth hormone and bisphosphonates resulted in improved linear growth, increased growth velocity and, increased bone mass acquisition. **Keywords:** OSTEOGENESIS IMPERFECTA, BONE MASS, GROWTH VELOCITY.

Osteogenesis imperfecta (OI), also known as brittle bone disease, can be defined as a heterogeneous group of diseases characterized by bones that fracture easily, often from little or no apparent trauma, with variable severity and presumed or proven defects in collagen type I biosynthesis. In addition to fractures, people with OI often have muscle weakness, joint laxity, skeletal malformations, and other connective tissue problems. Genetic disorders involving the skeletal system arise through disturbances in the complex processes of skeletal development, growth and homeostasis and remain a diagnostic challenge because of their variety. Almost 400 different forms of skeletal dysplasia have been described. ***The prevalence*** of OI is approximately 1 in 25,000 to

50,000 people in the United States. Because some infants die at birth and would not be included in these surveys, the birth incidence is slightly higher, perhaps 1 in 15,000 -18,000 births (1). ***Etiology.*** With rare exceptions, OI results from mutations in the type I collagen genes and is a dominantly inherited disorder. There are very unusual forms of OI that seem to be inherited in a recessive fashion, which means that each parent is a carrier and contributes one altered gene each to their child, who is then affected with OI. Type I collagen is the primary structural protein of bone and skin. In 1979, Sillence (2) divided OI into four types based on clinical, radiographic, and genetic distinctions. In 2010, Warman (3) reported additional types that do not involve a defect of type I collagen. Most OI cases are caused by heterozygosity of dominant mutations in one of the two genes encoding the chains of type I collagen (COL1A1 and COL1A2) (4), with quantitative or qualitative defects in the synthesis of type I collagen. Cartilage-associated protein, prolyl 3-hydroxylase 1, and cyclophilin B form an intracellular collagen-modifying complex that 3 hydroxylates proline at position 986 (P986) in the a1 chains of collagen (types I, II, and V); mutations in these essential cofactors cause alterations in the posttranslational chain modification and collagen folding, which are responsible for autosomal-recessive lethal or severe OI (5,6). Life expectancy varies per the severity of the underlying disorder and ranges from very brief to average. Because there is no cure for OI, its management or ***treatment*** currently focuses on minimizing fractures and maximizing mobility and independent function. Regarding the pharmacological approach, Bis are now indicated for children with OI (7). Administered orally or parenterally, these form a strong, rapid bond to hydroxyapatite crystals in bone and, by decreasing osteoclast activity and number, inhibit bone resorption and reduce bone turnover, although effects on bone formation occur as well. The positive effects of Bis on pain and mobility and on decreasing long bone fractures have been demonstrated. *Pamidronate* was the first Bis described, and authorized for use in OI children. A randomized controlled clinical trial with a different oral Bis, found that *Risedronate* increased areal BMD and reduced first and recurrent clinical fractures in children with OI (8,9). *Zoledronic acid*, a newer Bis with a longer half-life, greater potency, and more convenient dosing, is being studied in children with OI. Questions that remain to be answered include long-term side effects as well as impact on bone quality and bone health, the dosing schedule that maximizes benefits and minimizes detrimental effects, and the time to end or cut back therapy, as well as the benefit to patients with milder OI. Patients with OI should receive an appropriate contribution of calcium intake, phosphorus and vitamin D (10).

GH has a positive effect on bone growth and bone turnover by stimulating osteoblasts, collagen synthesis, and longitudinal bone growth (11); GH stimulates the expression of insulin-like growth factor 1 (IGF1) and IGF-binding protein 3 (IGFBP-3), which in turn regulates the synthesis of type I collagen. The positive height growth and an increase in skeletal volume and BMD reduce the number of fractures, this being the main significant therapeutic benefit. Animal studies, in a mouse model of OI with bone phenotype comparable to a mild form of OI in humans, showed that systemic rhGH injections (12) increased spine and femur length, produced significant changes in densitometry parameters and ameliorated the biomechanical structural properties of

bone. Despite rhGH action on bone turnover and bone mineralization resulting in an increase in BMD and on the growth velocity rate, few human studies have been performed using rhGH in patients with OI (13, 14, 15). There are no many controlled trials on combined rhGH and Bis treatment in OI patients.

MATERIAL AND METHODS

Retrospective study on eight children, six girls and two boys, from five families with OI type IA.

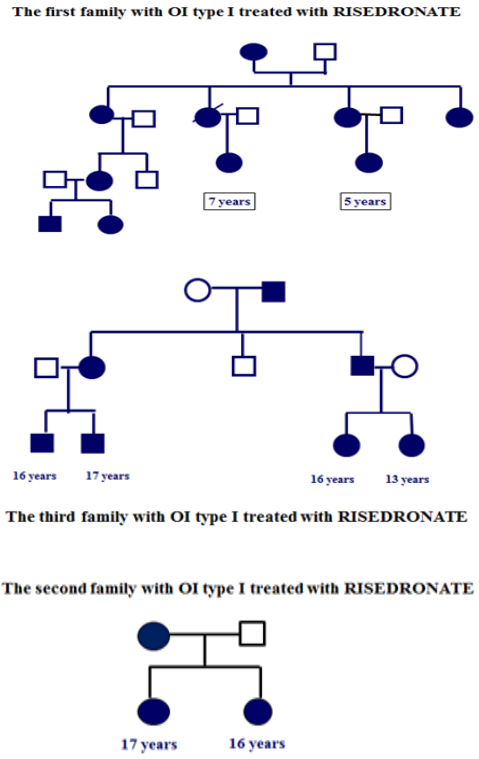

Fig.1. Family tree for each child included in the study

We have drawn the family tree for each child included in the study (fig 1). The X-ray exam confirmed the clinical diagnosis in all patients (fig. 2)

The children have been treated for 24 months with Risedronate. The children weighing under 30 kg received 35 mg Risedronate/14 days. The children weighing over 30 kg received 35mg Risedronate/ weekly. Two of the children (two girls) with significant growth disorders and in which over the past year growth velocity was under the 2 cm/year, have also received treatment with rhGH 0.3 mg/kg/ week. To monitor rhGH treatment compliance, the patients returned to the clinic every 6 months. The children treated only with Bis came every 12 months. All patients were evaluated for their auxological and clinical parameters-weight, height, body mass index, growth velocity, and Tanner stages-and the number of new peripheral or extra vertebral fractures. Bone metabolic parameters and bone mass measurements were determined at the time of enrollment after 12 and 24 months, and when the two girls started rhGH treatment, at every 6 months and finally at the end of rhGH treatment. Bone metabolic parameters were obtained/measured in the morning after an overnight fast. Serum Ca, P, alkaline phosphatase, parathyroid hormone (PTH), 25OHD, osteocalcin, C-terminal cross linking telopeptides of type I collagen, GH and IGF1 were determined; also measured were urinary Ca, P, and creatinine. Routine biochemistry samples, including creatinine and serum glucose, were collected. BMD was assessed at the lumbar spine and whole body using Hologic DXA-BMD with scans at baseline, and after 12 and 24 months of therapy. The DXA-BMD results were compared with the reference data for bone density; Z-score at baseline was in all cases over -2.5. Bone age (BA) was determined only in the patients on rhGH therapy.

a. The triangular skull, wormian bones. **b. 1-3.** Gracile long bones, thin dependent cortical **b.4.** recent fracture with unfit gag. **c.** Spinal deformities, multiple rib fractures.

RESULTS

At the beginning of the study, the mean lumbar BMD, expressed in SD, was lower than that of the normal population. Our results have indicated an increase in BMD of 13,2 % at girls and 22,6 % in boys after two years of therapy at the lumbar level. At the whole body the increase was 11, 5 % in girls and 25, 2 % in boys; this represented a reduction of the deficit of bone mass from -11 to -9 SDS in girls and from -9 to -4 SDS the boys (tab. I, II). No negative effects on the gastro-intestinal. Without new fractures under treatment. Children are still under the Bis therapy (14).

In our study, we followed the cases of

the two girls (cousins) which started the Bis treatment for OI type IA at the age of 7 and 5 years, respectively. In the girl aged 7, after the first 12 months of Bis treatment, the speed of growth was 2 cm/year; the speed of growth in the previous year being of 4.5 cm/year. In these circumstances, treatment with rhGH 0.3 mg/kg/week was initiated, which led to a speed of growth to 8.5 cm/year. The combined treatment was administered for 5 years, a final height of 160 cm being attained. Her cousin of 5 years, after a subnormal growth, at the age of 10 had a speed of growth of 2 cm/year and a growth retardation -2 SDS. Treatment with rhGH was initiated; her height after 5 years of treatment was 158 cm. In parallel we followed the acquisition of bone mass (whole body) which was very good: there was an increase in BMC of 478.19 g and BMD increased from 0.814 to 1.026 g/cm^2 reaching the normal ranges for age and sex (fig.3).

PTH, 25OHD and C-terminal cross linking telopeptides of type I collagen levels were in the normal range with no significant variations found during the study. Osteocalcin levels were in the low normal range at the beginning of the study, and remained at the same level. Serum Ca, P, alkaline phosphatase and urinary Ca and P have evolved within normal ranges. IGF1 levels were in the low normal range before therapy, and increased significantly after 12 months of rhGH therapy. After the study ended, the children have continued their treatment with Bis.

TABLE I.

Osteogenesis Imperfecta - Acquisition of bone mass under bisphosphonates at Lumbar Spine (LS)

Girls	Mean BMD LS (g/cm$^{2)}$	Mean BMD LS reference data (g/cm$^{2)}$	% deficit	% gain	SD deficit
Baseline	0.670	1.181	43.3	-	-9

Patient GMP under treatment with bisphosphonates and rhGH: 4-year course.

DISCUSSION

The aim of this retrospective observational study was to clarify if rhGH can ameliorate bone metabolism in patients with OI who had already benefited from ongoing Bis treatment. The rationale behind Bis treatment in OI is based on various bone metabolic data (7, 9), and on the fact that Bis have achieved significant clinical improvements in infants, children, and adolescents suffering from moderate and severe forms of OI. Their results in BMD gain and reduced fracture incidence have been proven by clinical trials, whereas their action in decreasing pain, increasing mobility, and even their positive impact on growth (16) has been seen in observational trials. It is known that rhGH stimulates bone apposition, obtaining an improvement in well-being, especially concerning skeletal integrity, and that it has positive effects on BMD and growth velocity (12). In our experience, BMD and growth improved with Risedronate treatment in our OI patients, compared with pretreatment (8). We decided to couple the prevalent inhibition of bone resorption by Bis with the anabolic effects of rhGH to analyze the possible advantages on BMD, projected bone areas, growth, and fracture risks. Bone mass increased at our children as demonstrated by the results obtained, an analysis of BMC (g) and BMD (g/cm^2) relating to age. As expected, during the two years of study Bis treatment resulted in improvements in lumbar spine and whole body BMD when treatment was based on Risedronate alone. With the combined Bis–rhGH therapy, densitometry results showed a significant, further positive increase in DXA-BMD at the lumbar spine and whole body after five years. There is limited literature regarding the experience with recombinant human GH in OI. One of the first attempts to treat OI patients with rhGH was made by Kruse and Kuhlencordt; their patients had an increase in periosteal new bone formation and intracortical bone resorption (assessed using histomorphometric of bone biopsies), with relatively enhanced osteoblastic activ-

ity (17). Following these results, no further study was reported in the literature until 1993 when GH–somatomedin axis activity was studied in a limited number of non-selected OI patients (13). Even if other studies had shown that IGF1 serum levels are mostly in the low normal physiological range, Marini et al. (13) found hypo activity of this axis (without a true GH deficit) in approximately half of their OI patients and treated them with rhGH. In a further study by this group, the authors concluded that there is also a group of type IV OI children who would benefit from rhGH treatment in terms of linear growth, bone matrix synthesis, and bone histomorphometric parameters.

CONCLUSIONS

Our experience suggests that the use of combined therapy of growth hormone and bisphosphonates has improved linear growth, increasing growth velocity. Also, combined therapy, increased the acquisition of bone mass measured by dual-energy X-ray absorptiometry at the lumbar spine and whole body, and reduced the incidence of peripheral fractures.

MALDI-TOF ALONE VERSUS MALDI-TOF COMBINED WITH REAL-TIME ANTIMICROBIAL STEWARDSHIP INTERVENTIONS ON TIME TO OPTIMAL ANTIMICROBIAL THERAPY IN PATIENTS WITH POSITIVE BLOOD CULTURES

Introduction: Matrix-assisted laser desorption ionization time of flight (MALDI-TOF) decreases time to organism identification and improves clinical and financial outcomes. The purpose of this study was to evaluate the impact of MALDI-TOF alone vs MALDI-TOF combined with real-time, pharmacist-driven, antimicrobial stewardship (AMS) intervention on patient outcomes. Methods: This single-center, pre-post quasi-experimental study evaluated hospitalized patients with positive blood cultures identified via MALDI-TOF combined with prospective AMS intervention, compared to a control cohort with MALDI-TOF identification without AMS intervention. AMS intervention included: real-time MALDI-TOF pharmacist notification, and prospective AMS provider feedback. The primary outcome was time to optimal antimicrobial therapy (TTOT). Results: A total of 252 blood cultures were included for final analysis: 126 in each group. MALDI-TOF + AMS intervention significantly reduced overall TTOT (75.17 vs 43.06 h, p <0.001), Gram + contaminant TTOT (48.21 vs 11.75 h, p <0.001), Gram - infection (GNI) TTOT (71.83 vs 35.98 h, p <0.001), and reduced overall hospital LOS (15.03 vs 9.02 days, p 0.021). TTOT for Gram + infection (GPI) was improved (64.04 vs 41.61 h, p 0.082). For GPI: reduced hospital LOS (14.64 vs 10.31 days, p 0.002) and length of antimicrobial therapy 24.30 vs 18.97 days, p 0.018). For GNI: reduced time to microbiologic clearance (51.13 vs 34.51 h, p <0.001), hospital LOS (15.40 vs 7.90 days, p 0.027), and ICU LOS (5.55 vs 1.19 days, p 0.035). Conclusion: In order to achieve optimal outcomes, rapid identification with MALDI-TOF combined with real-time AMS interventions is more impactful than MALDI-TOF alone. (Maya Beganovic, Michael Costello,Sarah M. Wieczorkiewicz. MALDI-TOF alone versus MALDI-TOF combined with real-time antimicrobial stewardship interventions on time to optimal antimicrobial therapy in patients with positive blood cultures. *Journal of Clinical Microbiology* 22 February 2017).

THE LINK BETWEEN QUALITY OF LIFE AND ECONOMIC ISSUES IN ANKYLOSING SPONDYLITIS

THE LINK BETWEEN QUALITY OF LIFE AND ECONOMIC ISSUES IN ANKYLOSING SPONDYLITIS (Abstract): Ankylosing spondylitis (AS) is an inflammatory rheumatic disorder which mainly involves the axial skeleton. The most important clinical features are: inflammatory back pain and peripheral joint involvement, but extra-articular manifestations that occur most often in the eyes, heart and lungs may also be present. Joint stiffness, pain and a progressive loss of spinal mobility can lead to severe functional limitations with subsequent negative impact on patients' quality of life. These symptoms can interfere not only with physical health, but also with social life and psychological wellbeing. Many studies took into consideration these aspects and tried to analyze the relationship between disease activity, functional impairment, work ability, interpersonal relationships and total costs of this debilitating disease. After many years of studying, the authors concluded that AS has a socio-economic impact on patients, society and healthcare system. **Keywords***:* ANKYLOSING SPONDYLITIS, QUALITY OF LIFE, ECONOMIC IMPACT, COSTS.

Ankylosing Spondylitis (AS) is a chronic inflammatory rheumatic disease belonging to the large group of spondylarthrites (SpA) alongside psoriatic arthritis, reactive arthritis, inflammatory bowel disease-associated SpA (IBD-SpA) and undifferentiated SpA. It affects mainly the sacroiliac joints and the axial spine. The most important clinical features are low back pain, joint stiffness, progressive loss of spinal mobility and peripheral joint involvement. All these symptoms can lead to severe functional limitations due to a significant impact on patients' quality of life. The onset of AS usually occurs in the second and third decades of life, when the patients are still active, affecting two times as many men than women. The disease has a prevalence of 0.1% to 1.4% worldwide (1).

AS has a significant socioeconomic impact on both the patient and society. When we speak about disability we refer firstly to the degree of inflammatory activity which determines stiffness, pain, sleeping disorders and fatigue and, secondly, to the degree of bony ankyloses which leads to a progressive loss of spinal mobility (2). These items have a significant impact on patients' quality of life and health status, negatively affecting patient's physical and

psychological wellbeing as well as their social life (3).

QUALITY OF LIFE IN ANKYLOSING SPONDYLITIS

Quality of life in patients with ankylosing spondylitis has been the main subject of many studies because the disease has a significant impact on patients' daily activities. Symptoms like joint stiffness, constant pain and functional impairment have a huge effect on the physical, psychological and social function of the affected people.

The self-administered questionnaires most commonly used in most of the studies to evaluate the activity of AS and the quality of life of patients are:

Bath AS Disease Activity Index (BASDAI) - a six-item questionnaire which evaluates the AS disease activity one week prior to the examination. It consists of six visual analog scales (VAS) and measures fatigue, spinal and peripheral joint pain, localized tenderness and morning stiffness. Each symptom has a VAS score (0= best, 10= worst) and the last two scores pertaining to morning stiffness are calculated as a mean score. The final BASDAI score is reported on a 0-10 scale, the greater the score, the worse disease activity (4).

Bath AS Disease Functional Index (BASFI) measures the functional impairment due to the disease. It consists of ten questions designed to measure joint function in everyday activities. All questions are scored 0 to 10 on a VAS and the mean gives the final BASFI result (5).

Bath AS Metrology Index (BASMI) evaluates hip and spinal mobility referring to cervical rotation, tragus to wall distance, lumbar side flexion, lumbar flexion (Schober's index) and intermalleolar distance. The final score ranges from 0 to 10 (6).

Bath AS Disease Global Index (BASG-s) consists of two questions that measure the effect of AS on patient's general health over the last six months and the last week (7).

AS Quality of Life Questionnaire (ASQOL) comprises 18 questions, each with a "yes/no" response format, scored "1" and "0" respectively, about the effect of AS-related pain concerning the management of the disease, relationships, mood, sleep, motivation, activities of everyday living, independence and social life (8). A better quality of life is reflected by a lower ASQOL score.

Short-Form 36 Health Survey (SF-36) is a measure of generic health status which evaluates eight domains of physical and mental health over the previous 4 weeks: physical functioning, physical role, bodily pain, general health, vitality, social functioning, emotional role and mental health. These questions are summarized in the: Physical Component Summary (PCS) and the Mental Component Summary (MCS). A better quality of life is indicated by a higher score (9).

All these questionnaires, which are the main tools in evaluating the disease activity and its impact on patients' everyday life, are used in many studies on the quality of life and economic issues of patients with AS.

A Polish study including 54 patients with AS aimed at obtaining patients' opinion on the factors which influence their quality of life (10). The study relied on a 12-item questionnaire on: ability to work, family and social life, pain perception, frequent hospital admissions or impediments to optimal management of AS. The results showed that pain is the main risk factor for a poor quality of life. Others risk factors include: family problems, social status (job loss, lower income), limitations

in performing home-based exercises or sexual life impairment.

Based on the SF-36 health questionnaire, a cross sectional study examined the health status in 100 AS Tunisian patients compared with the general population (11). They also used others disease-specific questionnaires such as: BASDAI, BASFI, BASMI, BASG-s to assess the disease stage. The results revealed: a poor quality of life in patients with AS, a better status in women than in men, mental health affected more than physical health, worse quality of life in the patients with low educational levels and better physical functioning in employed persons. Like other studies (12, 13), this survey demonstrated the association between great impairment in quality of life and high scores of BASDAI, BASFI, BASMI and BASG-s, the most important influence being attributed to pain, disease activity, mobility limitation and functional impairment.

Another important study on 962 patients with AS evaluated the quality of life using the well-known questionnaires (BASDAI, BASFI, BASMI, BASRI- Bath Ankylosing Spondylitis Radiology Index, MASES-Maastricht Ankylosing Spondylitis Enthesitis Score, ASQOL, SF-36) (14). The authors demonstrated that the quality of life was impaired in all patients. This is firstly due to low scores on bodily pain, physical role, general health and vitality subscales. They also showed a correlation between ASQOL and BASDAI, BASFI, BASMI, BASRI, MASES, fatigue, disease duration, overall pain and nocturnal pain. The most important variables with a negative impact on quality of life were: fatigue, disease activity, bodily pain and functional status. This study, like other studies (15, 16) demonstrated that smoking and sedentary life can negatively affect the quality of life of these patients, while a higher educational level can improve it.

Based on all these studies, we can affirm that AS is characterized by an increased impairment of the quality of life, affecting both physical and mental health. An early diagnosis and a proper treatment can improve the disease parameters responsible for the deterioration of quality of life.

ECONOMIC ISSUES IN ANKYLOSING SPONDYLITIS

On the other hand, AS has a significant socioeconomic impact on society and healthcare system, work disability becoming a frequent consequence of AS (17). The decrease in physical mobility is the main reason for the increasing costs associated with this disease (18). We can talk about direct costs that include: reported ambulatory care visits, hospitalizations, diagnostic tests (blood and imaging tests), medications, assistive devices, non-allopathic treatments (hydrotherapy, acupuncture, massage), riding to visits - transportation fees and paid household help or indirect costs which are related to productivity loss due to annual sick leave, number of days of activity limitation, retirees and homemakers (19, 20, 21).

An important study in Hong Kong evaluated the costs for 145 AS patients (22) and demonstrated that indirect costs are 62% of total costs. Of the direct costs, technical examination and a visit to the physician are the costliest. Also, they found out that 59% of the patients had additional expenses for non-traditional therapy and health products. This retrospective cross-sectional study revealed that many male patients (30%) and female patients (43%) were unemployed because of AS-related

work disability. Among the patients who had a job, a high percentage (86%) had taken on average an 8-day sick leave in the past year.

In this study, the patients were evaluated using BASDAI, BASFI and SF-36 questionnaires which highlighted that BASFI was correlated with direct costs while BASDAI has no all cost implications. So, functional impairment is an important driver of annual costs.

Numerous studies have also demonstrated that indirect costs are the most important in the group of total costs (23, 24, 25) and that physical functional impairment (measured by BASFI score) due to high disease activity is decisive in terms of total costs.

A US cross-sectional survey in 591 patients suffering from AS evaluated the work and family life of these patients compared with general population (PSOAS - Prospective Study of Outcomes in Ankylosing Spondylitis) (26). It showed that 13% of patients were work disabled, with a greater prevalence among women, twice as high compared with the general population. Disease duration (≥20 years) was associated with nonparticipation in the work force and work disability as well as with patients' level of education; those who had finished only high school were more affected from this point of view. Also, this study highlighted that AS has a big influence on the social life of the patients. The patients were more likely to be divorced (~30%) or single (never married) (~50%) and women with AS had fewer children than women in the general population.

A literature review conducted in Italy included the most important studies published between 2002 and 2012 on the economic impact of AS (direct and indirect costs) (27). The authors concluded that, in AS, indirect costs are the main component of total costs and that functional disability played a decisive role. In their survey, Younes et al. (28) found that direct costs are influenced by disease duration; job absence is closely linked to patient's age (over 40), disease duration (more than 10 years) and to civil status (more frequent in married people). Boonen et al. evaluated work productivity loss due to presentisms (number of days with productivity ≤50% at work) and sick leave (19) and found out that 73% of cases of sick leave were AS-related. Also, the authors noticed that direct costs were related to the length of hospital stay, number of doctor visits, medication used for treatment (disease-modifying antirheumatic drugs, anti-TNF drugs) or physical rehabilitation treatment (hydrotherapy, physiotherapy). Regarding indirect costs, they noticed that patients treated with anti-TNF drugs have less work days lost, lower sickness compensation and fewer disability pension (21).

Ara et al. evaluated the direct costs associated with disease activity using the BASDAI and BASFI questionnaires (29). They concluded that AS severity determines the annual cost per patient which is strongly related to BASDAI and BASFI scores, meaning that if the disease is active, the costs are higher.

CONCLUSIONS

Our clinical experience supports that most AS patients are young and have a significant physical disability measured by BASDAI, BASFI, HAQ, SF-36. Due to pain and functional impairment, they cannot perform activities of daily living and require long periods of sick leave. Also, because of pain and social exclusion, our patients often exhibit signs of emotional

instability and depression.

In summary, we can affirm that AS is a systemic inflammatory disease which is characterized by a severely impaired quality of life of patients and has high social costs. Disease activity contributes to functional limitations over time, so BASDAI, BASFI, pain and fatigue are the most significant variables related to the quality of life in patients suffering from AS. Functional impairment has been demonstrated to be the most important cost driver, having an important influence on family life as well as on work ability. Work disability is strongly influenced by patients' age and disease duration. Indirect costs are dominant in AS suggesting that these should be included in any cost assessment of new treatments.

To improve the general health of patients while decreasing total costs, doctors should take into consideration: patient education, pharmacological treatment combined with physical treatment, proper management of pain and fatigue and adaptation to the working place.

COLORECTAL CHEMOPREVENTION (Abstract). With over 1 million new cases diagnosed worldwide each year - incidence which seems to rise with the progressive westernization of lifestyles in Asian and African populations - colorectal cancer is the third most commonly diagnosed cancer in both men and women. Colorectal neoplasms and/or preneoplasms can be prevented by interfering with the various steps of oncogenesis, which begins with uncontrolled epithelial cell replication, continues with the formation of adenomas and eventually evolves into malignancy. The knowledge described herein will help to reduce and prevent this malignancy, which is one the most frequent neoplasms in some developed countries. Genetics, experimental and epidemiologic studies suggest that colorectal cancer results from complex interactions between inherited susceptibility and environmental factors. Primary prevention involves the identification of genetic, biologic, and environmental factors that are etiologic or pathogenic in the development of cancer, and subsequent complete or significant interference with their effects on carcinogenesis. K**eywords**: CHEMOPREVENTION, CARCINOGENESIS, COLORECTAL CANCER.

Colorectal cancer (CRC) is the second or third leading cause of cancer-related mortality in United States (1), incidence which seems to rise with the progressive westernization of lifestyles in Asian and African populations. In the past decade, therapeutic development has improved survival rates for patients with metastatic CRC, and many more treatment options exist for advanced disease. Many of these treatment options for advanced disease now include a combination of chemotherapy with targeted therapy. However, the fact that metastatic CRC remains incurable prompts investigators to explore a deeper understanding of the factors underlying cancer progression. The limited success achieved by only targeting tumor cells highlights the importance of understanding the role of the tumor microenvironment and its precise contribution to carcinogenesis. A major contributor to the tumor microenvironment is inflammation and inflammatory mediators. The recognition of chronic inflammation as the seventh trait acquired by tumor cells necessary for survival, growth, and metastasis (2-4) has intensified studies on the role of intratumoral inflammatory cells and proinflammatory cytokines in cancer progression. Chronic inflammation is now recognized as both a tumor initiator and promoter, and it has long been studied in relation to proinflammatory prostaglandins in colon cancer (5,

6). Clinical studies have shown that long-term use of nonsteroidal anti-inflammatory drugs (NSAIDS) reduces the risk of CRC by 40–50% (7), in part, by targeting cyclooxygenase-2 (COX-2), an enzyme required for prostanoid synthesis. COX-2 is overexpressed in the majority of CRCs (8, 9) and COX-2-derived prostaglandin E2 (PGE2) mediates various tumor promoting effects (6 - 8). PGE2 is the most abundant PG found in CRC tissue, and it has well demonstrated proneoplastic effects (12 - 14). PGE2 promotes tumor growth by inducing tumor cell proliferation, survival, migration/invasion (15 - 18) and by enhancing the development of a supportive tumor microenvironment. In CRC, the multistep process from normal colonic epithelium to an adenomatous polyp and ultimately to an invasive colon carcinoma is associated with or supported by the tumor microenvironment. The tumor microenvironment essentially consists of tumor-infiltrating cells, vasculature, extracellular matrix (ECM), and other matrix-associated molecules. Transformed epithelial cells modulate the functions of stromal cells with the overall purpose of facilitating their own growth, survival, invasion, and metastasis. This dependence or "addiction" of the cancer cells to the stromal components opens novel avenues for the development of potential therapeutic agents.

Cancer chemoprevention, as first defined by Sporn in 1976, is defined as the use of natural, synthetic, or biologic chemical agents to reverse, suppress, or prevent carcinogenic progression to invasive cancer (19). The success of several recent clinical trials in preventing cancer in high-risk populations suggests that chemoprevention is a rational and appealing strategy. Chemoprevention is divided into three groups. ***Primary prevention*** strategies seek to prevent malignancies (cancers) in an otherwise healthy population. These individuals may have a history that puts them at higher risk, such as a history of smoking or particular genetic mutations predisposing them to cancer development. ***Secondary prevention*** involves patients who have known premalignant (pre-cancerous) lesions utilizing medications or vitamins in an attempt to prevent the progression of these lesions into cancers. ***Tertiary prevention*** focuses on the prevention of new cancers in patients cured of an initial cancer or individuals who have been treated for premalignant lesions. Clinical trials of chemoprevention are based on the idea that interruption of the biological processes involved in carcinogenesis (the process of normal cells transforming into cancer cells) will inhibit this process and, in turn, reduce cancer incidence.

The ideal chemo preventive agent will not significantly alter quality of life, is inexpensive, safe, well tolerated, and effective. However, some chemo preventive drugs may have severe side effects in some patients, which is an issue when considering long-term administration of a compound to healthy people who may or may not develop cancer. Chemoprevention is thus of particular importance to genetically predisposed patients and to those patients who are especially susceptible to the environmental causes of colorectal cancer. Colorectal cancer is particularly suitable for prevention strategies because it is prevalent and associated with considerable mortality and morbidity (20). This cancer has a naturally history of transition from normal crypts through adenoma to overt adenocarcinoma occurring over an average of 10-20 years, thereby providing a window of opportunity for effective intervention

and prevention. Large bowel carcinogenesis occurs via a multi-step process, characterized by molecular and cellular alterations; interference with these processes forms the basis for chemoprevention, which attempts to target key molecular events along these pathways. Recent preclinical studies and clinical trials have provided data on the potential benefit of a number of nutritional or non-nutritional elements as well as drugs in the chemoprevention setting. The most important molecular markers/targets involved in signal pathways are polyamine 9ornithine decarboxylase), COX-2, iNOS, 3-hydroxy-3-methylglutatyl coenzyme A reductase, retinoid X receptor-alpha, estrogen receptor-beta, beta-catenin, 5-lipoxygenase, signal transducers and activators of transcription 3, NF-kB and hemeoxygenase-1. These can be also considered as biomarkers and/or surrogate endpoint markers in colorectal carcinogenesis and also enzymatic and molecular targets for colorectal malignancies (21,22). Currently, genetic information about cancer, molecular signaling and metabolic pathways has been translated into specific therapy that targets specific molecules for prevention. Developing new technologies to provide knowledge of the functions of non-coding RNA, such as small interfering RNA, microRNA and piwi interacting RNA, can form a basis for the development of novel chemo preventive agents that intervene at different steps during the multi-stage carcinogenesis process: preventing the initial mutation, blocking promotion to pre-malignant tumors, stopping progression from the pre-malignant state to in situ carcinomas or preventing invasion or metastasis. Because the early stages of tumor promotion and progression are rate limiting, successful targeting of molecular events during these stages can have a great impact on the outcomes.

Multiple lines of evidence indicate that aspirin and related NSAIDs are antitumorigenic and have the potential to prevent colorectal cancer. However, the mechanisms underlying this effect have yet to be fully elucidated. NF-κB is a ubiquitously expressed transcription factor that plays a critical role in cell proliferation and apoptosis. It was demonstrated that the RelA component of NF-κB is targeted to the nucleolus in response to NSAIDs and other pro-apoptotic stimuli of the NF-κB pathway and that nucleolar sequestration of RelA is required for the apoptotic effects of these agents. In present is currently studying the signaling networks involved in NSAID-mediated stimulation of the NF-κB pathway, nucleolar sequestration of RelA and the associated apoptosis. It was demonstrated that p38-mediated degradation of cylinD1/inhibition of CDK4 is important in this effect and so, this pathway is of particular interest. (19, 23, 24).

The disparity between the results of ACF formation and later tumor development by an agent was also documented previously on these parameters as a result of genistein administration. Genistein was thought to be a promising chemo preventive agent against colon carcinogenesis based on epidemiological observations that consumption of soybeans and soybean-based products containing a large amount of genistein might reduce the risk of colon cancer. While a short –term animal bioassay showed that genistein inhibits the development of azoxymethane-induced colonic ACF using tumors as end point demonstrated that dietary administration of this compound significantly enhances colon carcinogenesis. Celecoxib, a selective in-

hibitor of cyclooxygenase-2 and a promising chemo preventive agent against colon carcinogenesis, significantly inhibited BCAC in azoxymethane–treated rats, thus suggesting the possible application of BCAC as a biomarker.

CHEMOPREVENTIVE STUDIES

Despite promising data in epidemiologic studies, most dietary changes have not been successful in preventing colorectal cancer. Specifically, clinical trials have shown no benefit with fiber, beta carotene, vitamin A, C, and E interventions. Other studies suggest that calcium may prevent colorectal carcinoma by binding bile and fatty acids and inhibiting the proliferation of colonic epithelial cells. The Calcium Polyp Prevention Study evaluated calcium carbonate (3 g [1,200 mg of elemental calcium] daily) supplementation in 930 patients for four years and reported a decrease in the recurrence rate of colorectal adenomas. Although calcium supplementation led to a moderate reduction in risk of colorectal adenomas, it remains unclear whether this translates into prevention of invasive colorectal malignancies and a survival benefit.

Colon cancer prevention has now focused on novel targeted therapies, such as NSAIDs. Aspirin, an inhibitor of COX-1 and -2, has been studied in several large randomized studies, but the effect on colorectal cancer prevention is unclear. The US Physician's Health Study (25) which enrolled 22,071 physicians as participants, reported that aspirin had no effect on the incidence of polyps or colon cancer. However, Baron et al. (26) conducted the Aspirin/Folate Polyp Prevention Study, a randomized, double-blind, placebo-controlled trial of daily aspirin (325 mg and 81 mg) and daily folate (1 mg) in 1,121 patients with a recent history of colon adenomas. This trial demonstrated that the 81-mg dose of aspirin prevented recurrence of colorectal adenomas (47% placebo versus 38% aspirin 81 mg versus 45% aspirin 325 mg; $p = 0.04$). This translated into a relative-risk reduction of 19% in the 81-mg aspirin group and a nonsignificant reduction of 4% in the 325-mg aspirin group. This study also reported a relative-risk reduction of 40% in the 81-mg aspirin group for advanced lesions. Analysis of the folate intervention is ongoing. Also, Sandler et al. (27) reported the Colorectal Adenoma Prevention Study, which randomized 635 patients with prior colorectal cancer to 325 mg aspirin or placebo. Twenty-seven percent of the placebo group developed recurrent adenomas compared with 17% in the aspirin arm ($p = 0.0004$), for an adjusted relative risk of 0.65. Aspirin intervention delayed the development of recurrent adenoma and also decreased the number of recurrent adenomas.

Although the role of aspirin remains debated, the benefit of NSAIDs in chemoprevention has clearly been defined in certain high-risk subgroups. Aspirin and sulindac have been shown to reduce microsatellite instability in HNPCC cell lines carrying *h*MLH1, *h*MSH2, and *h*MSH6 mutations. In clinical trials of patients with FAP, sulindac (150 mg twice a day for nine months) was shown to decrease the number of polyps by 44% and decrease the diameter of the polyps by 35% ($p = 0.014$ and $p < 0.001$, respectively). In a study from the University of Texas MD Anderson Cancer Center and St. Mark's Hospital, United Kingdom (28) 77 patients with FAP (more than five polyps 2 mm in size) were randomized to receive placebo, 100 mg, or 400

mg of celecoxib twice daily. Celecoxib is a selective COX-2 inhibitor. Response to treatment was reported as the mean percent change from baseline. After six months, the 30 patients assigned to 400 mg of celecoxib had a 28% reduction in the mean number of colorectal polyps ($p = 0.003$) and a 30.7% reduction in the polyp burden ($p = 0.001$) compared with 4.5% and 4.9% in the placebo group, respectively. This positive result led to the FDA's approval of celecoxib in the treatment of patients with FAP. Other agents under investigation in colorectal chemoprevention include difluoromethylornithine (DFMO), which irreversibly inhibits ornithine decarboxylase and blocks cell proliferation. Ursodeoxycholic acid reduces the concentration of secondary bile acid deoxycholic acid in the colon and affects arachidonic acid metabolism. 3-hydroxy-3-methylglutaryl Coenzyme A reductase inhibitors are usually used in the setting of lowering cholesterol but also have antioxidant antiinflammatory properties and inhibit cell proliferation. Preclinical work in mutant APC murine models have shown that sulindac in combination with EGFR inhibitor EKI-785 can decrease intestinal polyps. Almost one-half the mice treated with the combination agents did not develop polyps. With the recent success of bevacizumab, an antibody to the VEGF-receptor in metastatic colorectal cancer, and cetuximab, an antibody to EGFR, further strategies will be applied to prevention. Studies have shown that individuals reporting a regular intake of aspirin and other (NSAIDs) have a reduced risk of developing colorectal polyps and cancer. It is thought that NSAIDs exert their chemo preventive effects in the colon by restoring a normal frequency of cell death. Because most colorectal cancers arise from adenomas (a type of colon polyp), it is believed that preventing adenoma formation can prevent cancer as well. In a study of 635 patients with a previous history of colorectal cancer who were randomized to receive either 325 mg of aspirin daily or placebo, there was a significantly reduced risk of development of an adenoma in the aspirin-treated group. However, adenomas still developed in some patients in the aspirin-treated group, and therefore aspirin should not be a substitution for surveillance colonoscopy. Another NSAID, celecoxib, has been shown to reduce the mean number of polyps by 28% in patients with the rare genetic disorder familial adenomatous polyposis. Because NSAIDS are associated with increased risk of gastrointestinal bleeding, renal impairment, and other toxicities, the United States Preventive Services Task Force (29) does not recommend NSAID use for the prevention of colorectal cancer.

CONCLUSIONS

Advances in delaying the development of colorectal carcinoma have been shown in patients with FAP with celecoxib treatment. However, the use of COX-2 inhibitors in the primary prevention of sporadic colorectal cancer is being studied in several ongoing trials. Current and future trials using celecoxib alone or in combination with chemotherapy and other biologic therapies are targeting several cohorts, including children with APC mutations, patients with FAP, HNPCC, prior colorectal adenoma, or prior history of sporadic adenomas. The use of celecoxib in the prevention of polyps has resulted in continued efforts to define a high-risk population and to implement a chemo preventive agent in the treatment of cancer. With regard to aspirin

use in the prevention of colon adenomas, two large randomized, placebo-controlled trials showed benefit. However, although the Aspirin/Folate Polyp Prevention Study and the Colorectal Adenoma Prevention Study reported positive results, a certain percentage of patients receiving aspirin intervention still developed colon adenomas. This suggests that aspirin use cannot be a substitute for colon surveillance and that further studies are necessary for effective colon cancer chemoprevention.

NEWS

A 9- PROTEIN RISK SCORE CAN EVALUATE THE CARDIOVASCULAR RISK

Myocardial infarction, stroke, heart failure are major pathology which occur among patients with heart disease. In a prospective cohort study, researchers have assessed the cardiovascular risk by different causes by determining the level of plasma proteins. The study included patients with stable coronary heart disease divided in two cohort: outpatients from San Francisco which are followed ≤11.1 years and Norwegian patient which are followed 5.6 years. Researchers tracked the occurrence of heart attack, stroke, heart failure and determined plasma levels of 1130 proteins. After statistical analysis, Peter Gunz and colleagues have validated a 9-protein risk score for 4-year probability of myocardial infarction, stroke, heart failure, and all-cause death. The results was compared with the refit Framingham secondary event risk score in predicting cardiovascular events and showed that the 9-protein risk score performed better than the refit Framingham score. Authors suggested that additional studies are needed to determine the accuracy of this score depending on levels of cardiovascular risk in patients with stable CHD (Peter Ganz, Bettina Heidecker, Kristian Hveem, Christian Jonasson, Shintaro Kato, Mark R. Segal, David G. Sterling, Stephen A. Williams. Development and Validation of a Protein-Based Risk Score for Cardiovascular Outcomes Among Patients with Stable Coronary Heart Disease. *JAMA*. 2016;315(23):2532-2541).

MUSCULOSKELETAL IMPAIRMENT IN HYPOTHYROIDISM (Abstract): This article contains bibliographical data concerning the rheumatic clinical manifestations in hypothyroidism: polyarthralgias, lack of recent skill of fine movements of the hands, carpal tunnel syndrome or tarsal, degenerative arthropathy or acute type (gout, chondrocalcinosis), adhesive capsulitis (frozen shoulder syndrome), generalized muscular stiffness, hypothyroid myopathy, secondary osteoarthritis, Dupuytren's contracture, "trigger finger" (also called as stenosing tenosynovitis or trigger thumb) etc. and data on the short history, epidemiology, of these disorders. Review include 60 bibliographical sources. **Keywords**: PRIMARY HYPOTHYROIDISM, MUSCULOSKELETAL IMPAIRMENT, RHEUMATIC DISEASES.

Thyroid hormones (THs) are vital role for maintaining the body's homeostasis. Thyroid hormones are among the key regulators of metabolism, adjusting the amount of proteins, carbohydrates, fats and minerals used by the body (1). Thyroid hormones play an important role in the development, maturation and maintaining morpho-functional integrity of the musculoskeletal structures (2). At the same time the decreasing synthesis of thyroid hormones leads to multiple negative effects on the entire system of the body functioning (1). Hormonal deficiency has unfavorable effects on bone formation and modeling, with consequences on the neuromuscular function and bone density. The relationship between musculoskeletal impairment and those of thyroid contains more aspects, among which, is, certainly, the imitation of the rheumatic diseases (2).

Currently thyroid gland pathology is considered one of the most common endocrine diseases in structure (3). A major endocrine pathology, involving various organs, frequently associated with musculoskeletal impairment presents, primary hypothyroidism (hT) (4, 5, 6, 7, 8, 9).

SHORT HISTORY

The relationship between arthritis and thyroid disease is known for a long time, in particular, the appearance of association with hypothyroidism (10). It is described for the first time in 1892, as the hypothyroid myopathy with endemic cretinism in children by E. Cocher, subsequently, defined as Kocher-Debré-Sémélaigne syndrome. In 1897, Johann Hoffman, for the first time, described a similar syndrome in adults, in a patient after thyroidectomy, which was later named in honor of this

researcher (11, 12). The relationship between thyroid disorders and shoulder pain was noticed in the first half of the 20th century (13). In 1960 was described the arthritis association with subclinical hypothyroidism, in the same time with the introduction of radioimmunoassay examination for thyroid stimulating hormone (TSH). The description of thyroid autoantibodies in the 50-s and 60-s of the last century forms a new stage in association of autoimmune thyroid disease (AIDT) with other diseases (14).

EPIDEMIOLOGY

In the Republic of Moldova, the thyroid pathology is ranked at the moment, the second disease as frequency among endocrine affections, leaving the first place only for diabetes. Comparing to year 2000, by 2006 the number of patients with thyroid pathology doubled (15). According to the data of specialized literature, 2-6% of the population suffer from hypothyroidism (16). The prevalence of subclinical hypothyroidism in the general population ranges between 1,3% -17,5%, depending on age and sex of the patient. The incidence of subclinical hypothyroidism is higher in women than in men, increasing with age and reaching 21%, in women, and 16% in men, aged over 74-years-old (17). Epidemiological studies indicate that the global prevalence of manifest hypothyroidism in population is 0,2-2%, subclinical 7-10% among women and 2,3% among men. In the group of older women, the prevalence of all forms of hypothyroidism can reach 12% or more (3). The estimates of the study conducted by NHANES (National Health and Nutrition Examination Survey) III highlight the prevalence of hypothyroidism in the US population which constitutes 4,6% in general population (0,3% clinical and 4,3% subclinical). In addition, this study found that prevalence rates increase with age and may approach up to 20% in women, from the general healthy population in the postmenopausal period (18). According to the results of a similar study conducted in Norway, the prevalence of diagnosed hypothyroidism is 4,8% in women and 0,9% in men (19).

According to I. Atroshi et al. (20) the prevalence of carpal tunnel syndrome (CTS) in the general population is 3,8%. However, M. Cakir and co-workers (6), reported that 9,5% of patients with thyroid disease have CTS, this phenomenon is more common among patients with hypothyroidism (30,4%). Women are affected more frequently (21). According to other studies, carpal tunnel syndrome occurs in approximately 30% of patients with hypothyroidism (22, 23).

Arthropathy occurs in 20-25% of patients with myxedema (8). Dupuytren's contracture, limited joint mobility and CTS are more common in patients with hypothyroidism, which are- 21,7%, 8,7% and 30,4%, respectively, and the "trigger finger "(TF), occurs in 10% of patients with subclinical hypothyroidism, which correlates with positive anti-thyroid peroxidase (anti-TPO) antibodies (6). Men are affected 7 times more often than women by Dupuytren's contracture, especially those aged over 40-years-old (24). The prevalence of fibromyalgia in AITD is determined at 30 to 40% of the patients (25, 26, 27).

CLINICAL MANIFESTATION

Rheumatic diseases are increasingly recognized as having an important role in de-

termining the health state of the population, and by diverse spreads, these diseases can be ranged from simple localized pain to the onset of disability movement (28).

Rheumatic clinical manifestations, produced by hypothyroidism are: polyarthralgias, lack of recent skill of fine movements of the hands (29), CTS (rarely tarsal), degenerative arthropathy or acute type (gout, chondrocalcinosis), adhesive capsulitis (frozen shoulder syndrome), generalized muscular stiffness, hypothyroid myopathy (2, 30), secondary osteoarthritis (OA) (31), Dupuytren's contracture, TF (also called as stenosing tenosynovitis or trigger thumb) (6), and of association with autoimmune diseases (vitiligo, rheumatoid arthritis (RA), Sjögren's syndrome, systemic lupus erythematosus (SLE), chronic active hepatitis, systemic sclerosis), which can dominate the clinical picture and serve as the only manifestation or symptom of the disease (32). According to V. Nasonova and N. Bunchyuk (33), in hypothyroidism, some patients may develop knee ligamentous weakness device, and Baker's cyst formation. Arthropathy is manifested by stiffness, joint swelling, sometimes the appearance of non-inflammatory joint effusion of articular cavity. Rheumatic manifestations can occur even in euthyroid patients, but more frequently in patients with hypothyroidism, in comparison with healthy persons without affecting the thyroid gland (34).

Carpal tunnel syndrome occurs when there is a compressing of the flexor tendons and the median nerve that travels through the carpal tunnel, patients usually present with pain, numbness or tingling in the median distribution (in the first two fingers and the side of the median third). These symptoms may worsen especially at night or at wrist flexion. In cases of prolonged physical activity**,** a weakness or atrophy of the thenar muscle may occur (35). Bilateral carpal tunnel syndrome has been reported in hypothyroidism by JC Jr. Chisholm (36), and an increased joint laxity, due to a hyaluronate deposits frequently found, this fact is reported by R. Ionescu (21).

Tarsal tunnel syndrome, with medioplantar nerve damage, is rarely observed (2). In these cases the patient complains pain such as burning and tingling in the big toe, planting area. Pains are nocturnal and may radiate to the back of the calf. The pain may improve while walking (24). The mechanism leading to compression is due to the accumulation of glycosaminoglycans in the surrounding tissues (2, 37).

Dupuytren's contracture is a painless condition that occurs marked thickening of the palmar aponeurosis, flexion contractures of the ring and little fingers (24, 38).

Stenosing tenosynovitis - is the most common cause of pain and disability at the level of hand. It affects flexor tendons of the fingers II-V and the long flexor of the thumb. Tenosynovitis occurs leading to fibrosis and constriction of the first fiber annular ring which covers the metacarpophalangeal (MCP) joint, being affected sliding tendon, causing pain and locking finger in flexion, especially in the morning, crepitations could be heard in the mobility (24).

Adhesive capsulitis is a painful condition, which is characterized by pain on movements and restriction in all dimensions, in the absence of joint damage. The progression of the disease has three phases:

• Painful phase- gradual onset of diffuse shoulder pain irradiated mobilization especially in the level of trapezius muscle. Sub-

sequently, the pain becomes nocturnal, waking the patient up from sleep for weeks - months;

• Adhesive phase (the stiffness). The pain becomes less severe, no longer appears in garaging or during the night, but still discomforting and feeling pain at the end of the movement. Limited movements of the gleno-humeral external rotation, internal rotation, and abduction becoming evident - up to one year;

• Resolution phase (thawing). The pain is less intense, the dominant symptom is limiting the movements of the shoulder.

A clinically useful indicator of the capsulitis presence is pain appeared during passive shoulder external rotation (21, 24).

Suffering pains. The simplest manifestations are the most common joint morning stiffness and eventual degenerative effusion. Accelerating speed of erythrocyte sedimentation rate for other reasons in some cases leads itself to confusion with rheumatoid arthritis (39). Rarely, the artropathy is monoarticulary or erosive, interestingly the interphalangeal joints can to mimic severe arthritis (40, 41). In some cases, calcium pyrophosphate dehydrate crystals were found in synovial fluid, but the condro-calcinosis association and its acute event (pseudogout) is not so frequent as in hyperparathyroidism and hemochromatosis (42). There are disputes over, whether or not there is random nature of the association between hT and chondrocalcinosis (39, 43, 44). However McCarty (45), a recognized researcher in chonrocalcinosis, says that the presence of calcium pyrophosphate dehydrate crystals in the joints is probably the most frequently associated with hT, and only then with hyperparathyroidism, hemochromatosis, and respectively, with hypophosphatasia. It was stated that in primary hT, in comparison with the general populations, there is indeed an increase in both the frequency of hyperuricemia and gout. In hT, it is affected kidney pool, by lowering the uric acid removal. hT was suspected as the trigger gout attacks (46). The symptomatology is alleviated through suppression of neutrophils (47). Hypothyroidism is linked to an increased incidence of fractures (48). It still remains controversial whether thyroid hormone replacement therapy also has adverse effects on bone. A review of 63 studies could not resolve the debate. Therefore, there is insufficient evidence on the effect of levothyroxine on the bone mineral density (BMD) (49).

After Bland et al. (50), in hT is usually affecting knees, MCP and proximal interphalangeal (PIP) joints, and as well as metatarsophalangeal (MTP), talocrural (TC) joints, without the presence of inflammatory synovitis. These impairments depend on TSH increase of the hyaluronic acid and the synthesis of proteoglycans in patients with hT (8, 50). Most cases of arthropathy change in hypothyroidism are found in adult, involving knees and hands, while the hip and femoral epiphysis occurs more frequently in children (7). Usually in hT, the syndrome of dolor palpation is missing. Generally, it affects symmetrically the knees, radiocarpal joint, small joints of the hands (PIP and MCP) and MTP joints. In some cases, there is a destructive arthropathy localized mainly in the PIP joints and less distal interphalangeal (DIP) joints (33).

In secondary OA, patients have "mechanical" type pain, stiffness from inactivity, limiting mobility, joint instability, crackling or grating sensation (crepitus)

highlighted by palpation or audible (31). In adults with hypothyroidism, joint pain can reveal an aseptic bone necrosis. Rubinstein and Brooks (51), described five patients with hypothyroidism, who were evaluated for a period of time ranging from 1 to 16 years-old, experiencing joint pain, which later were diagnosed with radiological and histological with aseptic bone necrosis. The bones involved were unilateral or bilateral femoral neck in three patients and two - to carpal bones (lunate bone or crescent) (51). Pretibial myxedema is presented in the form of painless nodules of pink or bright red color, of various sizes, being placed on the pretibial surface, which can have a similar aspect to *erythema nodosum* (21).

Muscle myopathy (hypothyroidism). In this condition, the most often reported symptoms by patients are: pain, cramps, stiffness, slight fatigue, and muscle weakness. On physical examination can be revealed muscular hypertrophy, proximal muscle weakness, delayed deep relaxation phase of tendon (52). At the initial examination, there is an increase in muscle mass of several groups of muscles, including the trapezius, deltoid, rectus capitis, and gastrocnemius (32). Stiffness and muscle weakness in myopathy are diffuse (53, 54). Generalized myalgias, when accompanied by painful trigger points may suggest this diagnosis, but these nonspecific symptoms may also be an initial hT phase (55, 56). Muscle pain and a feeling of "numbness" of the muscles are frequently and aggravated by cold exposure (57). A rare clinical disorder of myopathy in severe hT is Hoffman syndrome, which is manifested by severe muscle stiffness, increased muscle mass (pseudohypertraphy), variable muscle weakness, is accompanied by high levels of creatine kinase (58). Among of muscle symptoms of - muscle proximal myopathy (hypothyroid myopathy) occurs in 25-79% of cases in adult patients with primary hypothyroidism (22, 35, 59). According to Alakes's studies et al. (4), highlighted musculoskeletal manifestations in 120 patients with primary hypothyroidism constituted: bodily pain and myalgia - 83,33% of patients, muscle cramps and stiffness - 83,33%, back pain - 50%, arthralgia - 25%, adhesive capsulitis - 20,8%, limited joint mobility - 16,67%, myopathy - 8,33%, CTS - 6,6%, TF- 4,1% of Dupuytren's contracture - 3,33% and tarsal tunnel syndrome in 1,6% of patients. Associated rheumatologically manifestations were determined as follow: osteoarthritis - 66,7% of cases, mild inflammatory arthritis involving wrist joint - 50%, RA - 16,67%, SLE - 8,33%, fibromyalgia - 5%, Raynaud's phenomenon - 1,66% and the mixed connective tissue disease - at 1,66% of patients (4). A study conducted by Soy Mehmet et al. (60), in a group of 65 patients who were diagnosed with autoimmune thyroiditis, including 70% - with hypothyroidism demonstrated that the recorded rheumatic symptoms were as diverse as fibromyalgia - 34%, recurrent aphthous stomatitis - 18%, OA-12%, keratoconjunctivitis sicca and xerostomia - 10%, CTS - 10%, Raynoud's syndrome - 6%, inflammatory arthritis - 6%, autoimune - diseases 18%.

CONCLUSIONS

The relationship between hT and rheumatic diseases is significant and essential in the diagnosis and treatment of patients. The knowledge of spectrum of extra glandular clinical manifestations (including osteo-articular manifestations) is an im-

portant step in the management of patients with hT. However, thyroid dysfunction should be considered in the differential diagnosis in different musculoskeletal manifestations but the investigations of antithyroid antibodies should be a component part of screening the patients with joint problems, because they can serve as early signs at the presence and prognosis of the disease.

ANEMIA IN INFLAMMATORY BOWEL DISEASE: MORE THAN AN EXTRAINTESTINAL COMPLICATION (Abstract). The most common hematologic complication of inflammatory bowel disease (IBD) - ulcerative colitis and Crohn's Disease is anemia. Anemia in patients with IBD may be a result of iron, vitamin B12 or folate deficiency; anemia of chronic disease and hemolytic anemia are other causes in these patients. Factors contributing to the development of anemia include chronic gastrointestinal blood loss, vitamin B12 malabsorption secondary to terminal ileitis, folate deficiency as a result of sulfasalazine therapy. Approximately 30% of patients with IBD have hemoglobin levels below 12g/dl. The risk of developing anemia relates to disease activity, given that blood loss and inflammatory anemia are triggered by intestinal inflammation. In the management strategy of IBD patients with anemia it is important to distinguish between the different types of anemia in order to decide an appropriate manner of treatment. **Keywords:** INFLAMMATORY BOWEL DISEASE, ANEMIA, IRON DEFICIENCY, INFLAMMATORY ANEMIA.

Crohn's disease and ulcerative colitis are chronic inflammatory diseases of the gastrointestinal tract, mainly affecting the small intestine and colon, which progress with relapse and remission (1). IBD is associated with extraintestinal manifestation in more than 25% of cases, including malnutrition and anemia (1, 2).

Anemia is a clinically significant state which could impair quality of life or work capability and it represents a serious comorbid condition associated with other diseases or even death (1, 3). There are two major types of anemia in IBD patients: iron deficiency anemia and inflammatory anemia called until recently anemia of chronic disease. Moreover, mixtures of the two types are commonly found in these patients (3, 4, 5).

Epidemiology of anemia in IBD. The reported prevalence of anemia in IBD is highly variable ranging from 15% up to 75% depending both on patient subgroup and definition of the disease. In hospitalized patients to prevalence is up to 70%, while in outpatients the reported prevalence is only 15% (4, 6).

Clinical manifestation. Patients may present with a diversity of symptoms and

sign among which the most relevant are weakness, fatigue, dyspnea, tachycardia, headaches. These signs overlap the sigs of the underlying disease (7, 8, 9) (tab. I).

Causes of anemia in IBD. The main types of anemia in IBD patients are iron deficiency anemia and inflammatory anemia or anemia of chronic disease (3).

TABLE I

Clinical consequences of anemia in IBD patients

Fatigue	**Motility disorder**	**Impairments in quality of life**
Dyspnea	**Nausea**	**Loss of libido / impotence**
Tachycardia	**Anorexia**	**Impairments in physical condition**
Headache	**Menorrhagia/amenorrhea**	**Reduce energy efficiency during physical activity**
Dizziness	**Weight loss**	**Impairments in cognitive function**

Iron deficiency anemia mainly results from chronic intestinal blood loss due to chronic inflammation of the intestinal mucosa and from reduced iron uptake from enterocytes (impaired absorption) (6, 7). Intestinal inflammation leads to a decreased serum iron level and therefore to a reduced availability of iron for erythropoiesis (6, 9). In addition, inflammatory status causes decreased iron uptake from the intestinal mucosa, hence, providing a multipart two-way pathophysiologic mechanism between iron deficiency and inflammation (3, 4).

In patients with ileal Crohn's disease, absorption of vitamin B12 and/or folate may be impaired and all these condition frequently overlap (6, 10). Similarly, anemia in IBD patients may be induced by specific therapy-thiopurines, 5-ASA derivatives and/or by hemolysis (6, 9, 11) (tab. II).

Anemia workup. Full blood count, serum ferritin and C-reactive protein (CRP), are minimum requisite to identify anemia, an inflammatory relapse or iron deficiency at an early stage (7). Diagnostic measurement of blood count and CRP has been part of screening recommendations in IBD patients (11, 12). Patients in remission should be followed-up every 6 to 12 month, while active disease needs measurements at least every 3 months (11). Patients with extensive ileal Crohn's disease, ileal resection or ileal-anal pouch need proper follow-up. Serum vitamin B12 and folic acid levels should be measured every 6 to 12 month (7, 8, 9) (tab. III).

TABLE II

Etiology of anemia in IBD patients

Iron deficiency	**Regular**
Anemia of chronic disease	
Vitamin B_{12} deficiency	**Common**
Folate deficiency	
Drug induced 5-ASA; Thiopurine	
Hemolysis	**Infrequently**
Myelodysplastic syndrome	
Aplastic anemia	

The initial workup of anemia starts with the evaluation of MCV in order to distinguish between microcytosis (iron restricted anemia - iron deficiency and/or inflammatory anemia) and macrocytosis (B12 or folate deficiency) and also normocytosis (anemia of chronic disease) (8).

Platelet and white blood cell counts should be measured to reveal pancytopenia (12).

Serum ferritin level reflects the iron stores. Iron deficiency anemia is present when serum ferritin level is below 30 μg/L and hemoglobin level below 12g/L for non-pregnant females and below 13g/L for males (8).

Therefore, serum ferritin level can be used to detect iron deficiency; a drawback is that ferritin is a marker of acute inflammation and has to be evaluated together with CRP, as elevated ferritin may be due to a flair of inflammation or a superimposed infection (8, 12).

TABLE III
Serum markers of anemia in IBD patients

Mean corpuscular volume (MCV)
CRP
Serum Vitamin B_{12}
Serum Folate
Ferritin
Transferrin
Transferrin saturation (T-Sat)
Hepcidin
Soluble transferrin receptor concentration (StFR)

The diagnosis of iron deficiency anemia in IBD patients may be difficult mainly when both iron and inflammatory anemia are present. In this case, laboratory measures of iron status may be unreliable, as the presence of intestinal inflammation affects the parameters of iron metabolism (12).

In IBD patients with anemia even transferrin concentration may not be elevated as in pure iron deficiency anemia, due to the low albumin levels found in patients with intestinal inflammation (13).

Active IBD determines elevated hepcidin levels. Hepcidin blocks intestinal iron absorption and also reduces the release of iron from stores resulting in inflammatory anemia (11, 14).

Thus, a serum ferritin level between 30 and 100 μg/L in the presence of anemia and high CRP level indicates a mixture of iron deficiency and inflammatory anemia (14). On the contrary, a serum ferritin level over 100 μg/L together with anemia and elevated CRP level indicates pure inflammatory anemia (14).

T-Sat is a measure of the iron content in the circulating transferrin. A T-Sat below 16% indicates a suboptimal source of iron for erythropoiesis (14). T-Sat level provides an indirect indication of the degree of iron use in the bone marrow but does not provide evidence of the iron stores (2). In IBD, T-Sat is used in the anemia workup in combination with ferritin and CRP, at a lower cut-off point <16% (along with ferritin level <30 μg/L suggests iron deficiency) (13).

Testing for increased **s**TfR distinguishes between these two types of anemia but it is not generally available yet. A high diagnostic power of sTfR or sTfR/log ferritin ratio in differentiating iron deficiency from inflammatory anemia has been suggested by several studies (13).

Drugs commonly used in IBD treatment may have myelosuppressive effects: direct (thiopurine) or indirect (antifolic effect of sulfasalazine) (11). Sulfasalazine inhibits erythropoiesis by different mechanisms: hemolysis, aplasia and/or folate absorption (12, 13). A mild anemia may be detected in patients treated with thiopurine drugs (aza-

thioprine or mercaptopurine) (8, 14).

Management of anemia in IBD. The correlation between disease activity and level of anemia is well known. Consequently, the most significant measure in the treatment of patients with IBD and anemia is the specific treatment of the underlying disease (12, 15).

Inflammatory anemia is a common cause of anemia among hospitalized IBD patients with active disease. Treatment of non-iron deficiency anemia may include correction of IBD specific treatment, nutritional supplements, treatment of infections and, in selected cases, erythropoiesis-stimulating agents (13, 14).

In IBD patients on biological treatment (infliximab, adalimumab) the response to therapy has been shown to determine improvement of erythropoiesis, by significantly increasing the serum transferrin level (2). Colectomy is reserved for intractable, anti-TNFα-resistant ulcerative colitis. Folic acid and vitamin B12 deficiencies, another cause of non-iron deficiency anemia, should be treated in order to avoid anemia especially in patients with Crohn's disease, ileal resection and ileal-anal pouch (14).

Red blood cell transfusion may be considered when hemoglobin is < 7g/dL or above if risk factors and/or fatal comorbidities are present (9, 15). Nowadays transfusions in IBD patients are restricted to the severe attack of ulcerative colitis with severe anemia and hemodynamic instability, surgery for Crohn's disease, in the presence of severe comorbidities (14, 15).

Iron replacement treatment should be started immediately after iron deficiency anemia is diagnosed. Treatment options for iron deficiency anemia are intravenous iron supplementation or oral iron administration (2, 16) (fig 1).

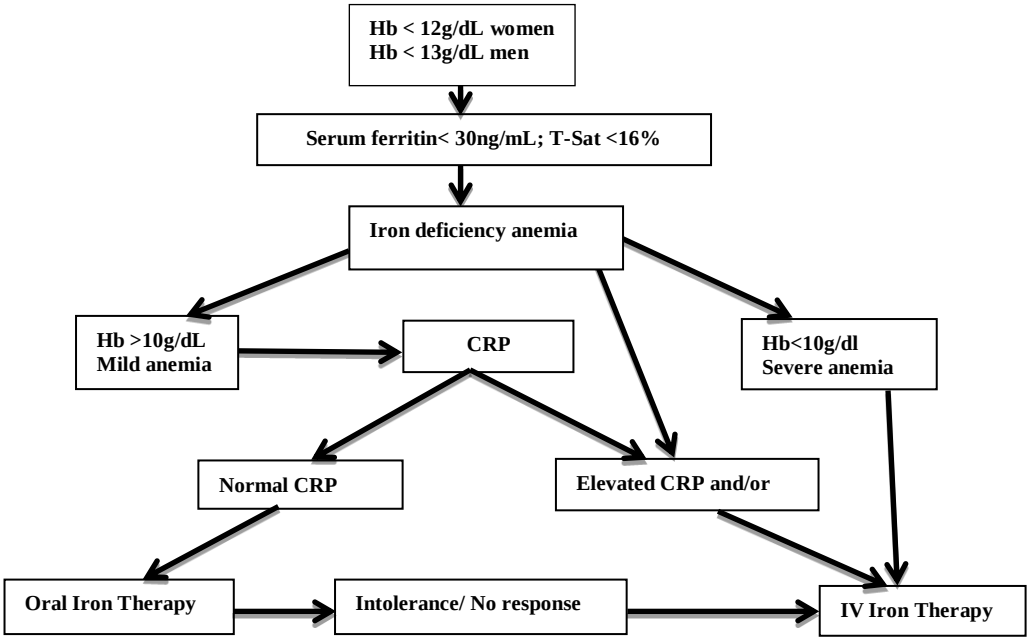

Fig. 1. Treatment strategies for IBD patients with iron deficiency anemia.

The therapeutic goals in iron deficiency anemia are to normalize hemoglobin, ferritin, and T-Sat levels, replenish iron stores (ferritin>100 μg/L) and improve quality of life (17). After the initiation of martial therapy, reticulocyte count will rise in the next 7-9 days and hemoglobin in one month (18).

Oral iron therapy is indicated in patients with mild anemia, hemoglobin > 10g/dL and remission in which oral iron absorption is not affected (17). There are many limitations of oral iron therapy: intolerance, noncompliance, worsens disease activity (14, 19).

Therefore, intravenous iron is the treatment of choice in iron deficiency anemia. According to the guidelines and consensus statement, in IBD patients intravenous iron supplementation is the preferred route. The advantage of intravenous iron therapy is better tolerance, compliance (usually single dose) and rapid reversal of anemia (18, 20, 21).

Ganzoni formula is useful to estimate iron requirements (2): Iron deficit (mg) = Body weight (kg) x [target Hb - actual (g/dL] x 2.4 + iron stores (500mg)

CONCLUSIONS

Our analysis of the literature studies revealed that anemia is the most common extraintestinal complication of IBD. It can increase the hospitalization rate in IBD patients and can affect quality of life and work capability.

An important goal for the IBD practitioner is to use anemia markers in order to accomplish the highest diagnosis yield of anemia in IBD patients. Anemia in IBD is usually a complex manifestation of a mixed type of iron deficiency and inflammatory conditions. The gastroenterologist should keep in mind other causes of anemia especially in small intestine involvement- vitamin B12 and folate deficiency. The pathophysiological causes of anemia in IBD include malabsorption, malnutrition, inflammation, intestinal resection, drug adverse events.

Iron deficiency anemia is common in IBD patients and is difficult to diagnose in the presence of inflammation. Intravenous iron therapy is a preferable option especially in active IBD patients and moderate-severe iron deficiency anemia.

ENDOTHELIAL DYSFUNCTION ASSESSED BY LASER DOPPLER POST-OCCLUSIVE HYPEREMIA IN CHRONIC KIDNEY DISEASE PATIENTS (Abstract): This study was intended to investigate the microcirculation endothelial dysfunction through a laser Doppler method (PORH post-occlusive reactive hyperemia) in patients with chronic kidney disease. **Materials and methods**: The study included 299 patients diagnosed with chronic kidney disease, which were divided into three groups: hemodialysis patients, peritoneal dialysis patients and patients with chronic kidney disease stages 3-4. Endotelial dysfunction was assesed with the Laser Doppler Perfusion Monitor type device (Periflux System Monitor 5001). **Results:** The values of the parameters we evaluated with postocclusive reactive hyperemia were altered in all patients with chronic kidney disease. In the dialysis groups there was no statistically significant correlation between parameters we tested by measuring PORH and the method of renal replacement therapy or dialysis duration. The same was observed in patients with pre-dialysis chronic kidney disease. **Conclusions:** Post-occlusive reactive hyperemia, a novel method for assessing endothelial dysfunction on the microcirculatory system and early marker of cardiovascular damage requires more studies to validate in patients advanced renal disfunction. **Keywords**: CHRONIC KIDNEY DISEASE, ENDOTHELIAL DYSFUNCTION, POST-OCCLUSIVE REACTIVE HYPEREMIA.

Chronic Kidney Disease (CKD) is characterized by structural or functional abnormalities of the kidneys, with a minimum duration of three months, which has serious consequences on the health of the individual, in the initial stages most patients being asymptomatic. Chronic kidney disease has long been under-diagnosed (1). Chronic kidney damage is a cardiovascular risk factor, which is associated with high morbidity and mortality, decreased quality of life and increased costs of health and social care (2). For this reason, in the last years, there was a significant increase in the interest of the early detection of kidney damage. The substrate of the initial changes in CKD, one of the most important cardiovascular risk factors, is represented by the endothelial dysfunction in close relationship with oxidative stress, inflammation and atherosclerosis (3,4). Endothelial dysfunction is an early phenomenon in atheromatosis, which precedes structural changes and clinical manifestations. For this reason, early detection of endothelial dysfunction is of major importance, since it

represents the initial event of atherogenesis (5,6). The detection and understanding of vascular changes may contribute to the development of therapeutic strategies to delay, stop or even regress vascular lesions and therefore have a particularly important impact on the clinical outcome of patients with renal impairment (7.8). The objective of the study was to assess endothelial dysfunction in advanced CKD patients using laser-Doppler post-occlusive reactive hyperemia (PORH).

MATERIALS AND METHODS

The study included 299 patients diagnosed with different CKD stages. The subjects were divided into 3 groups: 1) Stage 5 CKD patients, who were treated by hemodialysis (HD), 3 sessions / week, 4 hours/session, in "Dr. C.I. Parhon" dialysis center; 2) Stage 5 CKD patients, who were on peritoneal dialysis (CAPD – continuous ambulatory peritoneal dialysis); 3) patients diagnosed with CKD stages 3-4 who were periodically evaluated in the Nephrology Ambulatory of "Dr. C.I.Parhon" Hospital Iasi. The exclusion criterias were: patient's age <18 years; refusal to participate; psychiatric disorders that may affect patient compliance; dialysis duration <3 months; terminal stage malignancies; patients who had chemotherapy in the past 12 months; debilitating disorders (neurodegenerative diseases); systemic infections; acute coronary syndromes or strokes in the last 3 months. Each participant has completed a data acquisition paper.

Endothelial dysfunction was evaluated by a non-invasive laser Doppler method. In the study, we used the device Laser Doppler Perfusion Monitor (LDPM) type Periflux System 5001 (Perimed, Sweden). This device uses a low power laser signal with wavelength of 780 nm. For measurements we used the minimum value of the constant of time (0.2 seconds) and for the calibration, the manufacturer's calibration kit. Registration and data processing were done using the software offered by the manufacturer (Perisoft, Perimed). LDPM Monitor uses two optical fibers: one is the laser signal source for the skin, and the second fiber receives the reflected light from the tissue. The signal strength of the received laser signal depends on blood perfusion in that tissue.

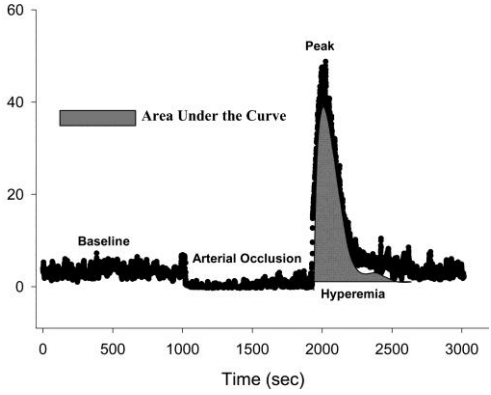

Fig. 1. PORH (Post Oclusive Reactive Hyperemia) measurement

PORH evaluation takes 9 minutes: the first 3 minutes we measure the baseline arterial blood flow in the forearm; next we practice the sudden occlusion of blood flow by inflating the sphygmomanometers' cuff, which is maintained for a further 3 minutes; then we immediately release the tensiometer's cuff measuring the blood flow for another 3 minutes. Parameters measured by this method are: RF (resting flow - basal arterial blood flow), BZ (biological zero - blood flow measured during obstruction), PF (peak flow - maximal arterial flow achieved after abrupt cessation of occlusion), TR (time to resting flow - the

time measured from the termination of the obstruction until the return of the blood flow to the basal value), TM (time to maximum flow- length of time from the release of the cuff until achieving maximal blood flow), TH (time to half recovery- length of time from the time of cessation of the obstruction until blood flow reaches the middle value between the maximum and the basal flow) (Fig. 1).

RESULTS

The average age of enrolled patients was 55.91+/-15.11 years; 46.5% (n = 139) were males. In the hemodialysis group (n = 168, 56.2% of subjects included in the study), mean age was 55.13 +/-14.27 years, the majority being males, 51.2% (n = 86). In peritoneal dialysis group (n = 73, 24.4% of all patients), mean age was 54.85 +/-15.06 years, the majority being females (64.4%). In the group of patients not on dialysis average age was 59.48 +/-17.17 years (Table I). There were no statistically significant differences between groups in terms of mean age (p = 0.132).

TABEL I

Description of the enrolled patients

		TOTAL	DIALYSED		NON-DIALYSED
			HD	PD	CKD
Number of patients		299(100%)	168(56,21%)	73(24,4%)	58(19,4%)
Average age		55,91+/15,11	55,13+/-14,27	54,85+/15,06	59,48+/17,17
Gender (%)	M	46,5% (139)	51,2% (86)	35,6% (26)	46,6% (26)
	F	53,5% (160)	48,8% (82)	64,4% (47)	53,4% (31)

The parameters of endothelial dysfunction in patients with chronic kidney disease

The detailed results of PORH parameters are presented in table II. In patients with peritoneal dialysis mean RF value was 32,33 significantly higher than in the other two groups (F = 7.44, p = 0.0007, 95% CI). There were no statistically significant differences between the RF values of hemodialysed versus non-dialysed patients (post-hoc LSD test, p = 0.904) (Table II, Fig.2).

We found statistically significant differences of BZ values between hemodialysed patients (5.44 ± 3.08) and peritoneal dialysed patients (6.88 ± 6.49) (post-hoc LSD test, p = 0.017) (Table. II, Fig. 3).

No statistically significant differences were found between PF values in hemodialysis, peritoneal dialysis and pre-dialysis patients (F = 0.709, p = 0.492) (Table II, Fig. 4).

We found statistically significant differences between the TR values in patients not on dialysis versus hemodialysis (post-hoc LSD test, p = 0.03) (Table II, Fig.5).

In non-dialysed patients TH values were significantly higher compared to TH values of patients on hemodialysis or peritoneal dialysis (post-hoc LSD test, p = 0.018). (Table II, Fig.6).

There were no statistically significant differences between the TM values in patients on hemodialysis or peritoneal dialysis compared to patients not on dialysis (F = 7.44, p = 0.0007) (Table II, Fig.7).

DISCUSSION

The link between chronic kidney disease and cardiovascular disease has already been demonstrated with chronic renal impairment beeing considered a major cardiovascular risk factor. Atherogenesis is one of the most important factors in this connection. Since endothelial dysfunction is a initiator phenomenon in atheromatosis and precedes structural changes and clinical manifestations, its early detection is crucial. Assessment of endothelial dysfunction can be done by invasive methods (determination of serum markers, plethysmography, termodilution method) or non-invasive methods done on macrocirculation (FMD – flow mediated dilatation) or microcirculation (PORH, iontophoresis) (9,10). The method used in this study has the advantage of being non-invasive, it can assess endothelial function in real time and it is also cheap and easy to be used in clinical medical practice.

In literature there are studies that investigated endothelial dysfunction on macrocirculation in patients with severe cardiovascular, metabolic and/or renal impairment. There are few data on the assessment of endothelial function on the microcirculation, mostly carried out on populations of diabetic patients and data are controversial (11, 14).

In a study on patients with chronic renal impairment, Stewart et. al, showed lower values of the parameters measured by PORH in subjects with renal pathology, but without being able to demonstrate the presence of significant differences between them and the group of subjects without renal impairment (12, 14).

Another study showed the presence of lower values for the parameters of post-occlusive reactive hyperemia in hypertensive patients with chronic kidney disease, and hypertensive patients with normal renal function, without being able to identify significant differences between these groups (13,14).

This study is one of the first to use Laser Doppler Post-occlusive Hyperemia in 299 patients in different CKD stages (predialysis and on dialysis). While no significant difference was found in “peak flow” and ”time to maximum flow” between the three groups, “time to half recovery” and “time to resting flow” were significantly higher in predialysis patients, while “resting flow” and “biological zero” parameters were higher in the peritoneal dialisys patients.

CONCLUSIONS

The present study showed that in patients with CKD there are changes in the values of the parameters evaluated by post-occlusive reactive hyperemia and these could be interpreted in the context of endothelial dysfunction in this population. For patients on hemodialysis and peritoneal dialysis, the correlation between the length of chronic kidney disease and dialysis time with the PORH parameters remained statistically insignificant, the same beeing observed in non-dialysed CKD patients, whose parameters were not statistically significant correlated with renal disease duration.

More studies are needed in CKD patients in order to validate this method of assessment of microcirculation endothelial dysfunction by PORH and to determine what parameter is a better predictor of future cardiovascular damage. The detection and understanding of early vascular changes in this population may contribute to the development of therapeutic strategies to delay, stop or even regress the vascular

lesions and therefore have a particularly important impact on the clinical outcome of patients with renal impairment.

ASSESSING CARDIAC PERFORMANCE IN PATIENTS UNDERGOING CARDIAC RESYNCHRONIZATION THERAPY (Abstract). **Aim**. To analyze the effects (clinical, electrical and ultrasound) of cardiac resynchronization devices, with or without an implantable defibrillator (CRT-P or CRT-D) on the patients with heart failure in our clinic**. Material and Methods:** We retrospectively analyzed 56 patients with NYHA functional class II-IV heart failure who underwent CRT-P or CRT-D in our clinic in the interval January 1, 2010 – June 1, 2014. To evaluate the effects of cardiac resynchronization therapy (CRT) we focused on measuring the QRS complex duration on electrocardiogram, left ventricular ejection fraction (LVEF) and the NYHA functional class assessment. These parameters were assessed immediately before intervention and one month after device implantation. Patient characteristics were expressed as mean $^{+}/_{-}$ 1 standard deviation or as number and percentage. Variables were compared by paired t test. A p wave value less than 0.05 was considered statistically significant**. Results:** QRS complex duration decreased from an average of 155ms to 129ms, a statistically significant narrowing of 25.4ms ($p< 0.0001$). The LVEF increased from an average of 28% to 35% ($p < 0.001$). A statistically significant improvement ($p< 0.0001$) in NYHA functional class was recorded. **Conclusions:** CRT is an important therapeutic approach, in our study 82.56% of the patients being considered responders due to improvement in the NYHA functional class and at least a 5% increase in the LVEF. A narrowing of the QRS complex on electrocardiogram was obtained in all patients classified as responders, so this simple method for measuring QRS complex duration can be used to assess the response to biventricular stimulation. **Keywords**: HEART FAILURE, CARDIAC PACING, THERAPY, BIVENTRICULAR STIMULATION.

Cardiovascular diseases (CVD) in general and heart failure in particular are major health problems due to the large number of patients and the incurred implications, the socioeconomic ones included. For this reason, the diagnosis methods, treatment and prognosis were also of interest. Technical developments during the past decades had a tremendous impact in contemporary medicine leading to further improvement of the diagnostic and therapeutic approaches. Cardiology is one of the most privileged specialties in terms of technological advancements. Cardiac resynchronization therapy (CRT) plays an important role in the treatment of patients with NYHA functional class II-IV heart failure despite the optimal medical treatment. During the last decade, long-term clinical effects of CRT were evaluated by randomized multicentre trials, such

as MUSTIC-SR (Multisite Stimulation in Cardiomyopathy Study), MIRACLE (Multicenter InSync Randomized Clinical Evaluation Trial), COMPANION (Comparison of Medical Therapy, Pacing and Defibrillation in Heart Failure trial), CARE-HF (The Cardiac Resynchronization Heart Failure trial). These trials showed that CRT improves symptoms and exercise capacity and decreases morbidity and mortality from cardiovascular causes. Yet, despite the fact that the indications for CRT are well described, at present the parameters/criteria for patient selection are not well defined, so that studies revealed that up to 30% of the patients did not respond to CTR.

The response to CRT can be assessed by various methods, but there is no agreement on which method best predicts response to CRT. The most widely accepted method is the clinical criteria of the New York Heart Association (NYHA) functional classification. Echocardiographically, the most commonly used method remains the assessment of LVEF. Recently, much more confidence is granted to the comparatively simple method of measuring QRS complex duration.

The aim of our study was to analyze the effects (clinical, electrical and ultrasound) of CRT, with or without an implantable defibrillator (CRT-P or CRT-D) in patients with heart failure in our clinic**.**

MATERIAL AND METHODS

Patient population. This prospective observational study included 56 consecutive patients referred to the Cardiology Department of the "Prof. Dr. George I.M. Georgescu" Cardiovascular Disease Institute, Iasi, Romania for CRT between January 1, 2010 and June 1, 2014. All patients were in NYHA functional class III/IV on optimal pharmacological treatment and showed reduced left ventricular systolic function (ejection fraction [EF] ≤ 35%) and a QRS complex duration of > 120ms. Patients with permanent atrial fibrillation and recent myocardial infarction (< 3 month) were excluded.

All patients were on an optimal pharmacological treatment with the maximum tolerated doses of digitalis medication, beta blockers, diuretics and ACE inhibitors. Resting 12-lead EEGs (at a paper speed of 25 mm/s) were acquired immediately before and one month after CRT device implantation. Clinical evaluation included assessment of NYHA functional class before and one month after biventricular pacing.

Echocardiographic data were obtained using a conventional ACCUSON CV 70 System (Siemens, Germany). In all patients echocardiography was performed at rest, in the lateral decubitus position, at baseline and six months after implantation. A standard evaluation of left ventricular volumes was performed in the apical 4-chamber view according to Simpson's rule method. To minimize the variability in measurements, all patients were evaluated by the same physician.

Classified as responders were those patients who presented at six month follow-up improvement by at least one NYHA functional class, an increase in LVEF of ≥5%, and decrease in left ventricular end-systolic volume (LVESV) and left ventricular end-diastolic volume (LVEDV) of ≥15%.

Patient characteristics were expressed as the mean $^{+}/_{-}$ 1 standard deviation or as a number and percentage. Variables were compared by paired t test. The value of p wave below 0.05 was considered statistically significant. Statistical analysis was performed using IBM SPSS statistical software (SPSS v.21.0, Mac OS X).

RESULTS

Baseline characteristics. The study population consisted of 40 men (71.42%) and 16 women (28.58%) with a mean age of 68.2 ± 10.4 years. 36.42% of the patients were in NYHA functional class IV and the mean QRS complex duration was 178.8 ± 18ms before cardiac stimulation (tab. I).

TABLE I

Baseline characteristics

Baseline characteristics	Patients (n=56)
Age (years)	62.8±10.4
Gender (male)	71.42
Gender (female)	28.58
QRS duration(ms)	178±14
NYHA III class (%)	62.8
Ischemic CMD (%)	28.32
LVEF (%)	20.3±6
DTDVS (ml)	224.8±68.5
DTSVS (ml)	176.3±49
LAv (ml)	72.8±10.5

The evolution of heart failure expressed by NYHA functional class after biventricular stimulation After CRT functional capacity was improved, most patients presenting at one month follow up an improvement by at least one NYHA functional class. So, if the inclusion rate for NYHA class IV patients was of 37.2%, after one month it decreased to 21.4% (fig. 1).

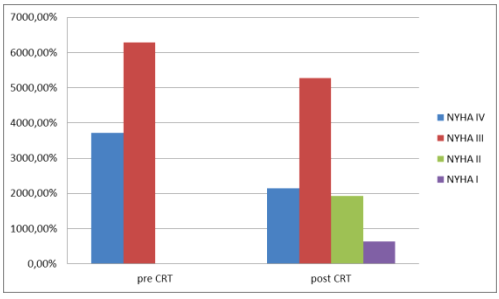

Fig. 1 .The evolution of heart failure expressed by NYHA functional class before and after CRT device implantation

The evolution of LVEF after CRT At baseline all patients had LVEF ≤35%. One month later, on echocardiographic assessment 82.26% of the patients showed an increase in LVEF of more than 5%, being classified as responders. 16.5% of them showed an LVEF improved by more than 15% - super-responders. 17.74% of the study patients showed no change in left ventricular systolic function - non-responders.

QRS duration on surface electrocardiogram decreased from an average of 178ms at baseline to 128ms, being a statistically significant correlation between QRS narrowing and the increase in LVEF. So, the patients with a narrowing of QRS complex of at least 30ms were classified as super-responders (16.5%), and those with a narrowing of 20 to 30ms as responders.

DISCUSSION

Heart failure is a syndrome characterized by cardiac remodeling; progressive left ventricular dilation, and consequently, reduced contractile function. Ventricular remodeling has been shown to be an independent negative prognostic factor. Atrial-ventricular and intraventricular delay further exacerbates left ventricular dysfunction and ventricular desynchronization favors mitral regurgitation and shortens left ventricular filling. Intraventricular delay is a pathophysiological process that directly depresses ventricular function, by causing ventricular remodeling and thus increasing morbidity and mortality. CRT has already been a major benefit in the treatment of heart failure. Numerous randomized trials have confirmed the important role of CRT on significant improvement in symptoms, increased exercise capacity, improved NYHA functional class (on average by 0.5-0.8 points) and increase by 20% in 6-minute walk distance. Quality of life was

significantly improved in all studies. Total mortality and hospitalization for heart failure were significantly reduced by CRT-P or CTR-D (COMPANION study).

The response to CRT can be assessed by various methods, but there is no agreement on which method best predicts response to CRT. The most widely accepted method is the clinical criteria of NYHA functional classification. Echocardiographically, the most commonly used method remains the assessment of LVEF. To these methods can be added the measuring of QRS duration on surface electrocardiogram as a simple but useful method of evaluation of clinical response to biventricular stimulation.

CONCLUSIONS

Cardiac resynchronization therapy is an important therapeutic option in patients with failure. In our study 82.56% of the patients were considered responders due to the improvement in NYHA functional class, increase in LVEF by at least 5% and narrowing of the QRS complex. The narrowing of the QRS complex on electrocardiogram was found in all patients classified as responders, so this simple method of measuring the duration of QRS complex can be used to assess the response to biventricular stimulation.

NEWS

ANTI-INFLAMMATORY EFFECT OF *STAPHYLOCOCCUS AUREUS* ON AIRWAY EPITHELIAL CELLS

A study by Chekabab *et al* examined the way bacterial cells modulate inflammatory responses in the setting of polymicrobial infections. Two major respiratory pathogens, *Pseudomonas aeruginosa* and *Staphylococcus aureus* can simultaneously colonize the airways of patients with chronic obstructive diseases (e.g. cystic fibrosis). The mechanism by which airway epithelial cells integrate bacterial stimuli in the case of polymicrobial colonization or infection is unknown. Since epithelial cell signaling is crucial for the activation of innate immune responses, the study examined the inflammatory responses to *P. aeruginosa* and *S. aureus* co-stimulations. Immortalized airway epithelial cells exposed to bacteria-free filtrates from *P. aeruginosa* induced a high synthesis of IL-8, while bacteria-free filtrates from *S. aureus* showed a minimal effect. However, in the case of co-stimulation with bacteria-free filtrates from *P. aeruginosa* and *S. aureus*, *S. aureus* filtrates inhibited IL-8 production induced by *P. aeruginosa*, showing potent anti-inflammatory effects. It also decreased IL-8 production induced by the TLR1/TLR2 ligand Pam3CysSK4 and dampened TLR1/TLR2-mediated activation of the NF-κB pathway. These results demonstrate that *S. aureus* modulates inflammatory responses in the setting of polymicrobial infections (Chekabab SM, Silverman RJ, Lafayette SL, Luo Y, Rousseau S, Nguyen D. *Staphylococcus aureus* Inhibits IL-8 Responses Induced by *Pseudomonas aeruginosa* in Airway Epithelial Cells. PLoS One. 2015;10(9):e0137753. doi: 10.1371/journal.pone.0137753. eCollection 2015).

QUALITY OF LIFE IN CROHN'S DISEASE PATIENTS (Abstract): **The aim** of the study is to assess the impact of Crohn's Disease (CD) on quality of life (QoL) patients with and to identify the significant modifications in QoL, depending on both the development particularities of CD and the epidemiologic parameters**. Material and methods:** a prospective study was conducted at the Institute of Gastroenterology and Hepathology Iaşi, between October 2011 and August 2014. The study enrolled 63 patients with CD. The CD diagnosis was based on clinical, biological, endoscopic and histological criteria. QoL was assessed by means of the IBDQ-32 questionnaire (*Inflammatory Bowel Disease Questionnaire*). **Results:** The total IBDQ score varied from 70 to 200, registering a slightly higher value in female patients. Parameters such as age, sex and smoking/ non-smoking status did not present significant differences in the IBDQ score. The values of the IBDQ score were in indirect, mild correlation with the CDAI score; over 49% of the subjects with higher CDAI had a lower IBDQ score. **Conclusions:** Except for the disease activity periods, the results of the studies investigating the impact of the various factors on the QoL in patients with CD are contradictory. Further research is needed in order to define the subgroups of patients likely to suffer from poorer QoL. **Keywords:** CROHN'S DISEASE, QUALITY OF LIFE, IMPACT.

Crohn's Disease (CD) is an inflammatory bowel disease (IBD) which may affect any part of the gastrointestinal tract, and may do so in a nonconfluent pattern. The inflammation in CD is typically transmural. The symptoms during the periods of flare-ups can be polymorphous, manifested through chronic diarrhea associated with blood and mucus, abdominal pain, chronic fatigue, fever and weight loss, often accompanied by extraintestinal manifestations (articular, cutaneous, hepatic, renal or ocular) (1).

The early onset and its chronic development, marked by periods of activity followed by remission, the pathologies associated, as well as the treatment of the disease, are all likely to affect the patients both physically and through the limitation of their social and emotional life, through their educational or professional activity (2).

Similarly to all other chronic disorders, this diagnosis is perceived as a verdict, a threat to their future, which is likely to inevitably affect their quality of life (QoL). Over the last period, there has been growing awareness of the psychosocial implications of chronic disorders, which have

previously been less known, or even ignored by the medical system (3). Although most of the times improvement in symptoms prevails over complete healing, the estimation of therapeutic success is essential through the assessment of the improvement in the patient's QoL. This is achieved through the use of questionnaires aimed at assessing QoL. Such methods are used especially in chronic disorders, in which the subjective improvement of the symptoms is one of the main objectives of the treatment (4).

Health-related quality of life (HRQoL) was defined as the functional effect of a disease and its treatment upon the patients, as perceived by the patients themselves. The need for HRQoL assessment emerged in order to achieve the objective of the medical act, more precisely, with a view to improve the patients' general state, respectively, their quality of life (6). HRQoL assessment contributes to quantifying the effectiveness of the medical act, taking into consideration its advantages and disadvantages (6).

The aim of the study is to assess QoL in patients with CD and to identify the significant modifications in QoL, depending on both the development particularities of CD and the epidemiologic parameters.

MATERIAL AND METHODS

A prospective study was conducted at the Institute of Gastroenterology and Hepathology Iasi, between October 2011 and August 2014. The study enrolled 63 patients with CD.

The CD diagnosis was based on conventional clinical features (diarrhea, associated or not with blood and mucus, abdominal pain, etc.), stool sampling in order to exclude infectious aetiologies, colonoscopy examinations by using the Mayo endoscopic score, biopsy sampling from the affected areas, and histopathological examinations. The disease activity was quantified by means of the CDAI score (*Crohn Disease Activity Index*).

QoL was assessed by means of the IBDQ-32 questionnaire (*Inflammatory Bowel Disease Questionnaire*), one of the questionnaires the most widely used in the assessment of HRQoL. The questionnaire contains 32 questions grouped into four fields: gastrointestinal symptoms (diarrheal stools, abdominal pain, rectal bleeding, and rectal tenesmus), systemic symptoms (fatigue, sleep disorders), emotional functions (depression, irritability, anger) and social functions (absenteeism, affected social status). The answers were marked on a scale from 1 (the worst) to 7 (the best). The total score ranged between 32 and 224. The lowest the score, the more affected the QoL (7).

Statistical analysis

The statistical treatment of the data was conducted by means of the SPSS 18.0 software as a perspective analysis, with no further adjustments for multiple testing, with a nominal significance defined as $p < 0.05$. The relationships between IBDQ-32 and the Mayo score are reported by the Pearson correlation coefficients. The qualitative differences were established by means of the Kruskal-Wallis test.

Ethical considerations

All the patients enrolled in the study signed an informed consent, through which they were given details on the aim of the study, its methodology, the risks and benefits incurred by the study, as well as information regarding the confidentiality of the results obtained.

RESULTS

The total IBDQ score varied from 70 to 200, registering an average value which was slightly higher in women (p=0.363) (tab I).

Gender distribution was approximately equal, the ratio of gender shares being 1/1. Both the average IBDQ score and its subgroups were slightly higher in the female patients (p>0.05). The patients' age did not influence the IBDQ score (p=0.987) (Fig.1).

Only 46% of the subjects were smokers, and the average IBDQ score did not present significant differences between the average values recorded in smokers (133.62±36.63) compared to non-smokers (143.47±27.44) (p=0.228) (fig.2).

The localisation and pattern of the disease did not influence the total IBDQ score (p=0.860, p=0.587). Nevertheless, slightly higher levels by subclass were highlighted in the patients with stenotic phenotype – B2 (p>0.05), (fig. 3). In the patients with *ileocolonic* location (L3), lower IBDQ score values were revealed, predominantly in the subgroups assessing QoL impairment by gastrointestinal symptoms, as well as impairment emotional function.

The individual values of the IBDQ score were in indirect, moderate correlation with the CDAI score; more than 49% of the subjects with a high CDAI score had a reduced IBDQ score (r= -0.494: R^2 =0.244; p< 0.001). The total IBDQ score was significantly lower in patients with moderate or severe flare (p=0.008). Assessed on subscales, gastrointestinal symptoms, systemic symptoms, emotional functions and social functions, the IBDQ scores were significantly lower in patients with severe flare (p<0.05) (tab. II).

TABLE I

Statistical indicators describing the IBDQ score by gender

Gender	N	Average	Standard deviation	Standard error	Confidence interval		Min	Max	p
					- 95%CI	+95%CI			
IBDQ									
female	32	142.59	31.260	5.526	131.32	153.86	76	195	0.363
male	31	135.16	33.053	5.936	123.04	147.29	70	200	
IBDQ-1 gastrointestinal symptoms									
female	32	30.66	7.998	1.414	27.77	33.54	14	46	0.397
male	31	28.94	8.029	1.442	25.99	31.88	15	46	
IBDQ-2 systemic symptoms									
female	32	33.50	8.527	1.507	30.43	36.57	16	48	0.315

DISCUSSION

Similarly to the data obtained from the literature, the study confirms the fact that the disease flare is the factor likely to have the highest impact on QoL in patients with CD. To date, it has been proven that severe disease flare influences QoL negatively, both in the patients with CD and in those with UC (8). In the present study, CD had a negative impact on all aspects related to the patients' QoL, which may lead to depressive states and anxiety during and after periods of flare-ups. The total IBDQ and the scores of its subscales were significantly lower in the patients with moderate and severe disease activity (p=0.008).

In our study, the age, gender and the smoking status did not influence the IBDQ total score and sub-scores. Some studies have shown that QoL is more severely affected in women compared to men with CD (9). Nevertheless, this finding was not confirmed in the present study. As far as smoking is concerned, it was proven that smoking patients with CD underwent a higher risk of post-operative recidive, with lower response to medication. Recent data has suggested that smoking induces modifications at the level of both the inborn and acquired immune system. Moreover, smoking is associated with distinct modifications in the gut micro biota in both IBD and the healthy patients (10).

Although in our study, age did not influence the QoL score, previous research has shown significant differences in the QoL scores between young and old patients (11, 12).

Besides the disease flare-ups, the IBD patients' age and gender are likely to have a significant impact on their QoL. Another study has shown that patients aged >50 years old presented a significantly lower QoL score compared to younger patients ($p < 0.001$) (13).

On the other hand, other studies have shown that younger patients, even those with mild disease flare, presented a more influenced QoL, as well as a higher degree of chronic fatigue, compared to older patients ($p = 0.06$) (14,15).

Additionally, the disease localisation and pattern did not have a statistically significant influence on the IBDQ score. However, the patients with ileocolonic CD presented lower IBDQ scores.

CONCLUSIONS

The results of our study confirm the data in the literature regarding impaired QoL in patients with CD. The total IBDQ score varied from 70 to 200, registering a slightly higher value in female patients. Parameters such as age, sex or the smoking/ non-

smoking status did not present significant differences in the IBDQ score. The disease flare ups had the highest impact on the QoL in patients with CD. The values of the IBDQ score were in indirect, mild correlation with the CDAI score; over 49% of the subjects with higher CDAI had a lower IBDQ score. Except for the disease activity periods, the results of the studies investigating the impact of the various factors on the QoL in patients with CD are contradictory. Further research is needed in order to define the subgroups of patients likely to suffer from poorer QoL.

THYROID FINE-NEEDLE BIOPSY: ASPIRATION VERSUS CAPILLARY (Abstract) Thyroid nodules are a common pathology of the thyroid gland. Thyroid fine-needle biopsy (FNB) is a technique used as the first step in the assessment of thyroid nodules. Some authors have demonstrated the superiority of nonaspiration compared with aspiration biopsy. **Aim**: The objective was to assess whether there are significant differences between the two thyroid biopsy techniques. **Material and methods:** The study group comprised 309 patients with thyroid nodules admitted to the Endocrinology Clinic of the Iasi "St. Spiridon "Hospital between 2005 and 2008 in which fine-needle nonaspiration or aspiration biopsy was performed. The slides were read by one pathologist. The smears were stained using the May-Grunwald-Giemsa method (MGG). The quality of smears obtained by the two sampling techniques was evaluated by using the scoring system developed by Mair. **Results and discussion:** No differences in smear quality between the two sampling techniques in terms of blood contamination, amount of cellular material, degree of cellular degeneration, degree of cellular trauma, and preservation of appropriate architecture were found. **Conclusion**: The results of this study show that the sensitivity and specificity of both techniques allow their use as standard screening methods for thyroid nodular lesions. **Keywords:** THYROID NODULE, THYROID CANCER, BIOPSY, THYROID.

Thyroid nodules are a common pathology of the thyroid gland. Fine-needle aspiration (FNA) is a technique used as the first step in the assessment of thyroid nodules (1). An alternative to this technique is fine-needle nonaspiration (FNNA) technique using capillary pressure to suck cells into the needle lumen. This technique was originally used for collecting cellular material from other organs such as liver or mammary gland. It uses a thin 25 gauge needle (0.50 mm outer diameter, 25 mm length) the cells being detached by the sharp edge of the needle and pushed into the needle lumen by the capillary pressure (2). Subsequently, the needle is removed and the cells are expelled on a slide. FNNA was for the first time used in the assessment of thyroid lesions by Santos in 1988 (3). Subsequent studies have given conflicting results on the effectiveness of the two methods (4, 5).Some authors support the superiority of FNNA compared with FNA. Among their arguments are less cellular and tissue trau-

ma and the reduced amount of background blood in smears. Also FNNA is less painful providing better patient compliance (6, 7, 8). Other authors have demonstrated that FNA is superior or equivalent to FNNA offering as arguments the reduced amount of cellular material obtained by FNA compared to FNNA (8).

The aim of this study was to assess whether there are significant differences between the two thyroid bioptic techniques.

MATERIAL AND METHODS

The study group comprised 309 patients with thyroid nodular lesions admitted to the Endocrinology Clinic of the Iasi "St. Spiridon" Hospital in the interval 2005-2008 in which one of the two techniques was performed. The slides were read by one pathologist. The smears were stained using the May-Grunwald-Giemsa method (MGG). The quality of smears obtained by the two sampling techniques was graded by using the scoring system developed by Mair and consisted in evaluation of blood contamination, amount of cellular material, degree of cellular degeneration, degree of cellular trauma and preservation of appropriate architecture. A score ranging from 0-2 was assigned to each of these criteria (tab. I).

TABLE I

Scoring system for the assessment of smear quality (4)

Criterion	Qualitative description	Point score
Blood contamination	Large amount – diagnosis greatly compromised	0
	Moderate - diagnosis possible	1
	Minimal- diagnosis easy	2
Amount of cellular material	Minimal or absent - diagnosis not possible	0
	Sufficient - diagnosis possible	1
	Abundant – diagnosis easy	2
Degree of cellular degeneration	Marked – diagnosis impossible	0
	Moderate -diagnostic possible	1
	Minimal – diagnosis easy	2
Degree of cellular trauma	Marked - diagnosis impossible	0
	Moderate - diagnosis easy	1
	Minimal –diagnosis obvious	2
Preservation of appropriate architecture	Minimal or absent - diagnosis impossible	0
	Moderate – diagnosis possible	1
	Excellent –diagnosis easy	2

Excluded from the study group were the patients in which thyroid biopsy was not completed with paraffin histology of surgical specimen obtained by the surgical removal of the thyroid gland. The cell samples obtained by fine needle biopsy and surgical specimens were processed and diagnosed in the Pathology Department of the "St. Spiridon" Hospital Iasi. The smears were assessed and classified according to Mair score, a score being assigned to every smear. The score (0-2) was considered C

(unsuitable for cytological diagnosis), (3-5) was considered B (suitable for cytological diagnosis) and (6-8) was considered and A (excellent for cytological diagnosis). The obtained scores were then compared between the two bioptic techniques, aspiration and capillary sampling. A total score ranging from 0 to 8 was assigned to each smear obtained by one of the two techniques. The obtained data were compared with the literature data and statistically processed using the statistical functions in *Excel* and *SPSS*. Because the variables did not have a normal distribution, for comparing the two methods the nonparametric chi-square test was used. Chi-square test is a nonparametric test that compares two or more frequencies in the same population. The accepted significance threshold was 95%, $p < 0.05$, but the lower this p value the stronger the significance. For the comparative evaluation we calculated the sensitivity, specificity, positive and negative predictive value of each of the two methods. The samples that could not be interpreted were excluded and the suspicious ones were considered malignant. The cytological diagnosis on each biopsy was compared with a diagnostically superior investigation, the "gold standard" in this study being the postoperative histopathological examination conducted in the Pathology Department of the "St. Spiridon" Hospital Iasi.

RESULTS AND DISCUSSION

A total of 309 patients were assessed by thin needle biopsy (287 women – 92.8 % and 22 men -7.2 %). In 34 patients (11%) biopsy was performed by aspiration (FNA) and in 275 patients (89%) by non aspiration (FNNA).

Cytologically, the massive blood contamination obscured the thyroid cell masses preventing microscopic examination, moderate blood contamination consisted of a moderate red blood cell mass mainly consisting of intact red blood cells together with intact thyroid cellular elements and minimal blood contamination was diagnosed in smears with isolated intact red blood cellular elements.

Of the smears obtained by fine-needle non aspiration (FNNA) 6.90%, confidence interval (CI): 4.46 to 10.53 showed massive blood contamination, diagnosis impossible, 66.54% (CI: 60.77 to 71.86) moderate blood contamination, diagnosis possible, and 26.54% (CI: 21.67 to 32.06) minimal blood contamination, diagnosis easy.

By aspiration technique massive background blood contamination, diagnosis impossible, was found in 2.94 % of the samples (CI: 0.52 to 14.91), moderate blood contamination, diagnosis possible in 58.23% (CI: 42.22 to 73.63), and minimal blood contamination, ideal for interpretation in 38.23% (CI: 23.90 to 54.95).

No statistically significant differences in the quality smears in terms of blood contamination were found between the two techniques ($p = 0.28$).

Amount of cellular material classified the smears into three categories: minimal, sufficient and abundant amount of cellular material.

The minimum amount of cellular material consisted of isolated thyroid cellular elements, less than 30 cells or free nuclei, sufficient amount of cell material was considered when the smear contained up to six groups of thyroid cellular elements, each group containing 10 thyrocytes, and the amount of cellular material was abundant when over six groups of thyroid cellular elements, each group containing 10 thyrocytes were visualized.

Of the FNNA smears 23.27% (CI: 18.66 to 28.61) showed minimal cellularity, diagnosis impossible, 47.63% (CI: 41.80 to 53.33) sufficient cellularity, and 29.02% (CI: 24.04 to 34.71) abundant amount of cellular material, ideal for diagnosis. Of the FNA smears 23.52% of cases (Cl: 12.43 to 39.99) showed minimal cellularity, diagnosis impossible, 41.17% of the cases (Cl: 26.36 to 57.77) sufficient cellularity, and 35.29% (CI: 21.48 to 52.08) abundant amount of cellular material, ideal for diagnosis.

No statistically significant differences in the quality smears in terms of the amount of cellular material were found between the two techniques (p = 0.71).

Degree of cellular degeneration: three categories were identified: marked, moderate and minimal degree of cellular degeneration.

In the marked degree of cellular degeneration the thyroid cellular elements are mainly represented by free nuclei and thyrocytes, the moderate degree of cellular degeneration is characterized by the presence of less than 6 cell groups of 10 thyrocytes showing intact cytoplasm, and the minimum degree of cell degeneration is considered in the presence of more than 6 groups of 10 thyrocytes with intact cytoplasm.

On FNNA smears the degree of cellular degeneration was marked, diagnosis impossible, in 24.36% (CI: 19.66 to 29.76), moderate in 58.9% (CI: 53.01 to 64.56) and minimal, ideal for diagnosis in 16.72% (CI: 12.78 to 21.59). With FNA the degree of cellular degeneration was marked in 23.52% (CI: 12.43 to 39.99), moderate in 47.05% (CI: 31.45 to 63, 26) and minimal in 29.41% (Cl: 16.83 to 46.16) of the samples.

No statistically significant differences in the quality smears in terms of the degree of cellular degeneration were found between the two techniques (p = 0.17).

Cellular trauma. Marked cellular trauma consisted of a marked degree of degeneration of cellular elements, most of them with free nuclei lysis and destroyed cytoplasm Moderated cellular trauma consisted of a moderate degree of degeneration of the cellular elements, most of them with free nuclei lysis and destroyed cytoplasm, the number of intact cell groups ranging for 1 to 6, and minimal cellular trauma was characterized by a low degree of degeneration of cellular elements, most of them with free nuclei lysis and destroyed cytoplasm, and over 6 groups of intact cells.

Of the FNNA smears 24.36% (CI: 19.66 to 29.76) showed a marked degree of cellular trauma, diagnosis impossible, 58.9% (CI: 53.01-64.56) a moderate degree of cellular trauma, and 16.72% (CI: 12.78 to 21.59) a minimal degree of cellular trauma, ideal for diagnosis.

In terms of cellular trauma 23.52% (CI: 12.43 to 39.99) of FNA smears showed marked cellular trauma, 47.05% (CI: 31.45 to 63.26) moderate cellular trauma, and 29.41% (CI: 16.83 to 46.16) minimal cellular trauma.

No statistically significant differences in the quality smears in terms of the degree of cellular trauma were found between the two techniques (p = 0.17).

Preservation of appropriate architecture. The smears were divided into 3 categories: minimal, moderate, and excellent preservation of appropriate architecture.

Smears with minimal preservation of appropriate architecture were those characterized by the presence of some cellular elements isolated, rare intact thyrocytes

arranged in large cell aggregates. Smears with a moderate preservation of appropriate architecture consisted of a single layer of thyrocytes in honeycomb or microfolicular arrangement. When some cellular elements were intact with well-preserved cellular border and intact cytoplasm the smear was considered as having an excellent preservation of appropriate architecture.

In 24.36% (CI: 19.66 to 29.76) of FNNA smears preservation of appropriate cellular architecture was minimal, non-diagnostic, moderate in 58.54% (CI: 52.64to 64.21) and excellent in 15.63% (CI: 11.82 to 20.39).

By FNA, preservation of appropriate architecture was: minimal, non-diagnostic in 23.52% (CI: 12.43 to 39.99), moderate in 50% (CI: 34.09 to 66.93) and excellent in 26.47% cases (CI: 14.80 to 43.11) of the smears.

No statistically significant difference in the quality smears in terms of the preservation of appropriate architecture was found between the two techniques ($p = 0.39$)

According to smear quality, 23.53% of FNA smears were categorized as C, unsuitable for diagnosis (score 0-2), 47.06% as B, diagnostically adequate (score 3-5) and 29.41% as A, excellent for diagnosis (score 6-8). Twenty-four percent of FNNA smears were categorized as C, unsuitable for diagnosis (score 0-2), 56.36% as B, diagnostically adequate (score 3-5), and 19.64% as A, excellent for diagnosis (score 6-8).

The difference in quality of the smear was not statistically significant ($p = 0.39$). When comparing the sensitivity and specificity of the two techniques we found that sensitivity was 71.43% (CI: 35.89 to 91.78) for FNA and 75% (CI: 56.64 to 87.32) for FNNA, and specificity was 91.67% (CI: 74.15 to 97.68) for FNA and 93.75% (CI: 89.65 to 96.33) for FNNA.

The differences in sensitivity and specificity between the two techniques were not statistically significant

Although cytology is less reliable than histopathology (9) thyroid biopsy is a minimally invasive investigation with a high sensitivity and specificity (10). There are several techniques of sampling cellular material, the most commonly used being fine-needle aspiration (FNA) and fine-needle non-aspiration (FNNA).

Both methods have at least theoretically advantages and disadvantages. FNA usually yields more material but also more blood contamination due to the applied aspiration which will affect the quality of the sample and implicitly the possibility of interpreting it, while FNNA may produce less material, but may cause less bleeding and produce a specimen of higher quality. However, both methods are equally used in practice.

What constitutes and adequate smear? Follicular cells are essential for a good interpretation, decreasing the number of false negative reports. Goellner et al (11) noted that the number of false negative results was lower or even eliminated by the presence of 5 or 6 groups of well-preserved follicular cells, with at least 10 cells per group.

Hamburger and Hussain (12) suggested the need of six cell groups, each containing an average of 16 cells while Nguyer et al. (13) required 10 cell groups each containing about 20 cells or 8-10 well preserved follicular fragments.

In our study approximately 24% of biopsy was considered diagnostically inadequate. There were no significant differences between FNA and FNNA in terms of the assessed parameters: background blood, amount of cellular material, degree of cel-

lular degeneration, degree of cellular trauma, and preservation of appropriate architecture. In studies conducted by Kamal and Santos a higher number of adequate smears were obtained by FNNA (8). Both studies found no significant differences between the two methods (14, 15).

CONCLUSIONS

Our study shows that the sensitivity and specificity of both techniques allow their use as standard screening methods for thyroid nodular lesions. The obtained results demonstrate that FNA and FNNA have similar efficacy.

KEY FACTORS INFLUENCING THE LEVEL OF JOB SATISFACTION AMONG OBSTETRICS AND GYNECOLOGY PHYSICIANS IN ROMANIA (Abstract): **Aim:** The purpose of this study was to identify the level of job satisfaction among obstetrics and gynecology physicians in Romania. **Material and methods**: Job satisfaction was measured using the Job Satisfaction Scale and personality traits were identified using the Big Five Inventory Socio-demographic variables were also considered to identify factors that can contribute to the level of satisfaction. The data analysis was performed using *SPSS Statistics v23.0.0*. **Results:** A low level of satisfaction was identified among obstetrics and gynecology physicians. 19.64% of doctors responded that they were satisfied or very satisfied with their job. Male doctors were more satisfied with their job than female doctors were (- t (110) = 2.00, p=0.05; 3.71 ± 0.82 vs 3.39 ± 0.59). Specialists were more satisfied than consulting doctors regarding overall job satisfaction (Mdif = 0.336, p=0.031). Statistical differences were identified among the variables insomnia, depression, and the use of pills to cope with stress. A high number of working hours and a high level of neuroticism were negatively correlated with job satisfaction. Extraversion and agreeableness were strongly related to job satisfaction. **Conclusions:** The results are important for obstetrics and gynecology physicians to explain the level of satisfaction related to their personality traits and for institutions to reconsider the important factors that could influence job satisfaction among doctors. **Keywords:** PERSONALITY TRAITS, JOB SATISFACTION, OB-GYN PHYSICIAN, NEUROTICISM, BIG FIVE INVENTORY, DEPRESSION.

The level of job satisfaction among medical specialties has varied over the years, because of health policies and changes in medical practice. Some studies show that high job satisfaction scores occur among dermatologists (1), geriatricians (2), pediatricians (3), forensic physicians (4), and ophthalmologists (5).

Job satisfaction for doctors is correlated with a high level of satisfaction among patients and increased compliance. Caring for patients, sense of accomplishment, continuity of care, autonomy, and having personal time are the most important factors associated with satisfaction with job (6). Satisfaction was found to be more linked to the level of autonomy than professional prestige (7).

Job dissatisfaction among physicians is associated with conflict, absenteeism, low

patient care rate, reduction in quality and quantity of work (8) and migration (9). Factors that influence doctors' satisfaction with their job are related to both environmental (institution, patients, activity, department) and psychological factors (personality traits, family issues).

Some statistics indicate that medical students and young doctors sometimes choose their specialty based on the quality of life assured by practicing it. For example, Lambert et al (10) found that younger physicians in England avoid surgical specialties and obstetrics and gynecology, because of the level of quality of life and the higher number of working hours. On the other hand, Schmidt (11) reported an 80% satisfaction rate among obstetricians and gynecologists in USA.

Bettes et al. (12) pointed out that obgyn doctors who are assisting delivery (vaginal or cesarean) are more prone to a low level of job satisfaction, because of the increased workload and decreased personal control. In the study of Kravitz et al. (13) higher career satisfaction was related to age greater than 65 years, academic activity, medical practice in small metropolitan areas, and the ability to obtain services. To increase satisfaction related to one's career and to help doctors cope with stress, providing training to junior physicians in this specialty has positive results on mental health and job satisfaction (14).

Personality traits in tandem with work values were found to predict specialty choice (15, 16) but some other researchers showed that personality does not have a strong influence on what individuals consider to be important in their work environment or on the level of their satisfaction with job (17).

The goal of this study was to identify the socio-demographic variables and personality traits (using Big Five Inventory measuring extraversion, agreeableness, conscientiousness, neuroticism, and openness) - that influence job satisfaction among obstetrics and gynecology physicians in Romania.

MATERIAL AND METHODS

Participants

The number of registered obstetrics and gynecology physicians who were working in public or private medical institutions was approximately 1,724 in 2016 (18). The subjects in our research study include 116 obstetrics and gynecology physicians, working in 10 departments across Romania. The number of doctors who answered the questionnaires and were included in the present study represents 6.72% of all registered doctors of this specialty in Romania.

Instruments

Physicians were asked to fill out a socio-demographic data sheet and to answer two questionnaires: *Job Satisfaction Scale* and *Big Five Inventory*. Before completing the questionnaires, the doctors had to sign an informed consent form that provided information about the research objective, data privacy, and the fact that the results were only being used for this study.

The *Job Satisfaction Scale* - JSS, (19) has 32 items and 3 dimensions: payment–promotion (14 items), management–interpersonal relationships (8 items), and organization–communication (10 items).

The personality traits were evaluated using the *Big Five Inventory* - BFI, (20,21). The instrument consists of 44 items corresponding to five personality factors: extraversion (8 items), agreeableness (9 items), conscientiousness (9 items), neuroticism (8 items), and openness (10 items). A Likert scale with 5 steps registered 1 as strong disagreement and 5 as strong agreement.

The other registered variables were age,

level of specialization (resident, specialist, or primary doctor), marital status (in a relationship or single), data about the partner (the partner is also a physician), number of children, number of years of experience in this specialty, teaching activity, number of hours of work per week, and number of shifts per month. Self-reported data about insomnia, the use of drugs to cope with stress, depressive periods in the past or present, and known chronic diseases were also reported.

Ethical approval

The research was approved by the Ethics Committee from the "Cuza-Voda" Obstetrics and Gynecology Clinical Hospital, Iasi, Romania. The present study is part of a larger study targeting professional and personal factors and their influences on ob-gyn doctors' wellbeing and their quality of life.

Statistical analysis

Statistical analysis of data was performed using *SPSS Statistics v23.0.0*. The *t* test for independent samples and One-Way ANOVA were used for the comparative analysis. Statistical difference was defined as $p<0.05$. For the correlational study, Pearson and Spearman correlations were used, and to identify the influence of personality traits and socio-demographic data on job satisfaction multiple linear regressions were used.

RESULTS

Socio-demographic and work-related data

A total of 35 men and 81 women were included in the study, Mage = 40.34 ± 12.11 (with a minimum of 26 and maximum of 70 years of age); 42 were residents, 11 were specialists, and 63 were physician consultants.

Regarding marital status, 31 declared that they were single and 95 that they were presently in a relationship. Almost 40% of them had a partner practicing the same profession.

TABLE I

Socio-demographic data

Variables		N (%)
Gender	male	35 (30.17)
	female	81 (69.83)
Age	≤ 30	40 (34.5)
	31-40	21 (18.1)
	41-50	31 (26.7)
	≥51	24 (20.7)
Level of specialization	resident	42 (36.21)
	specialist	11 (9.48)
	consultant	63 (54.31)
Marital status	In partnership	85 (73.28)
	Single	31 (26.73)
The partner is a doctor		45 (39.47)
Having children		76 (65.22)
Experience as O/G doctor (M years)		12.94 ± 10.94
Weekly work hours		56 ± 21
Monthly number of shifts		4.5 ± 2.2
Having academic activity		24 (20.69)
Number of simultaneous jobs	1	83 (71.6)
	2	25 (21.6)
	3	8 (6.8)

The average number of years working in this medical field was 12.94 ± 10.94. Regarding hours worked per week, we identified M = 56 ± 21 hours/week. The number of shifts per month was M = 4.5 ± 2.2 shifts (tab. I).

Psychological data

All subjects answered the BFI questionnaire, and 112 of 116 completed the JSS questionnaire.

Cronbach alpha scores for the JSS subscales are: 0.632 for payment–promotion, 0.786 for management–interpersonal relationships, and 0.727 for organization–communication. For overall job satisfaction, alpha Cronbach score is 0.837. For BFI, we obtained the following results for Cronbach's alpha coefficient: 0.802 for extraversion, 0.467 for agreeableness, 0.772 for conscientiousness, 0.769 for neuroticism, and 0.743 for openness to experience

Overall satisfaction score was 3.49 ± 0.68, which corresponded to a low level of job satisfaction. For the first factor, payment – promotion, the score of 2.78 ± 0.89 showed a very low level for this subscale, which means that they are not satisfied with the material rewards, other financial benefits, professional recognition, and promotions. Regarding the second subscale, management–interpersonal relationships, the score was 3.95 ± 0.86, which corresponds to a very high level of satisfaction. This score indicates that subjects were very pleased with the social climate within their institution and the relationships developed on both horizontal and vertical levels. The third subscale targets the way the tasks are defined and organized and the effort that is involved in accomplishing them. It also refers to communication and feedback. On this subscale, our subjects obtained a score of 4.15 ± 0.71, corresponding to a medium level of satisfaction (tab. II).

TABLE II

Results for *Job Satisfaction Scale* and *Big Five Inventory*

Instruments		Total	Male	Female
JSS	Payment - promotion	2.78 ± 0.89	3.10 ± 1.18	2.65 ± 0.70
	Management – interpersonal relationship	3.95 ± 0.86	4.12 ± 0.97	3.87 ± 0.81
	Organization - communication	4.15 ± 0.71	4.40 ± 0.79	4.04 ± 0.66
	Overall satisfaction	3.49 ± 0.68	3.71 ± 0.82	3.39 ± 0.59
BFI	Extraversion	3.71 ± 0.71	3.73 ± 0.72	3.69 ± 0.71
	Neuroticism	2.79 ± 0.71	2.67 ± 0.69	2.84 ± 0.73
	Openness	3.60 ± 0.57	3.60 ± 0.61	3.61 ± 0.56
	Conscientiousness	3.99 ± 0.59	4.05 ± 0.50	3.97 ± 0.63
	Agreeableness	3.85 ± 0.83	3.80 ± 0.55	3.87 ± 0.93

Self-reported information about having a chronic disease, depression, insomnia, and administration of drugs to cope with stress were also registered. A number of 46 (39.7%) of subjects declared that the suffer from a chronic disease, 15 (12.9%) had or have depressive symptoms, 41 physicians (35.3%) mentioned sleep-related problems and 12 of

them (10.3%) sustained that they use medicines to better adjust to stressful factors.

Gender

A significant difference was found for the gender variable regarding overall satisfaction (- t (110) = 2.00, p = 0.05). This indicates that men are more satisfied with their job than women are (3.71 ± 0.82 *vs* 3.39 ± 0.59). Significant differences were also found for the first and third subscales of JSS. Male doctors were more satisfied than female doctors regarding payment–promotion (3.10 ± 1.18 *vs* 2.65 ± 0.70; *t* (110) = 2.03, p = 0.049) and organization–communication (4.40 ± 0.79 *vs* 4.04 ± 0.66; *t* (110) = 2.44, p = 0.016). No significant difference was identified between men and women regarding the second subscale (management–interpersonal relationship).

The level of specialty

To analyze the differences among various medical specialties (residents, specialists, and consulting physicians), univariate analysis of variance (ANOVA) was used. We found that specialists are more satisfied overall with their job than consulting doctors were (Mdif = 0.336, p = 0.031) and management–interpersonal relationship subscale (Mdif = 0.459, p = 0.009). For the other two subscales, no difference was identified between the three specialty levels. No significant differences were found regarding all subscales and general satisfaction between residents and specialists or consultants (tab. III).

TABLE III

Comparative analysis regarding job satisfaction considering the level of specialty

JSS	Residents	Specialists	Consultants
Payment–promotion	2.84 ± 0.81	2.92 ± 0.51	2.72 ± 1.00
Management–interpersonal relationship	3.98 ± 0.78	**4.31 ± 0.26**	**3.85 ± 0.97**
Organization–communication	4.04 ± 0.67	4.43 ± 0.49	4.17 ± 0.77
Overall satisfaction	3.48 ± 0 .10	**3.77 ± 0.20**	**3.44 ± 0.08**

Insomnia, depression and use of medicine to cope with stress

The independent *t* test analysis revealed that significant differences between the subjects who self-reported sleep disorders regarding job satisfaction for all subscales and for overall job satisfaction, so we determined that doctors who experienced insomnia obtained lower scores. We also found that self-reported depression also produces differences in overall job satisfaction and the last subscale, organization–communication (tab. IV).

The results are important, because they indicate that sleep disorders determine significant differences in what determines satisfaction with professional activity. Also, it can be assumed that depression plays an important role in job satisfaction reported by obstetrics and gynecology physicians.

To analyze whether there are differences between doctors who use pills to cope with stress and those who do not self-administer stress medications. The results proved that significant differences only occurred with the third subscale, meaning that doctors who do not use pills to manage stress had higher levels of satisfaction regarding organization – communication: t (110) = - 2.08, p = 0.04 (Mwith = 3.75 ± 0.64 and Mwithout = 4.20 ± 0.71). For the other two subscales and for overall job satisfaction, no significant differences were found.

TABLE IV

Comparative analysis regarding job satisfaction considering *insomnia* and *depression*

JSS	Insomnia	Depression
Payment–promotion	t (110) = - 3.84, p = 0.000 (Mwith = 2.41 ± 0.57 and Mwithout = 2.98 ± 0.97)	t (109) = - 1.15, p = 0.24 (Mwith = 2.53 ± 0.61 and Mwithout = 2.83 ± 0.92)
Management–interpersonal relationship	t (110) = - 3.29, p = 0.001 (Mwith = 3.59 ± 0.75 and Mwithout = 4.14 ± 0.87)	t (109) = - 1.77, p = 0.07 (Mwith = 3.58 ± 0.61 and Mwithout = 4.01 ± 0.88)
Organization–communication	t (110) = - 4.38, p = 0.00 (Mwith = 3.77 ± 0.57 and Mwithout = 4.35 ± 0.70)	t (109) = - 2.23, p = 0.028 (Mwith = 3.76 ± 0.53 and Mwithout = 4.21 ± 0.72),
Overall satisfaction	t (110) = - 4.23, p = 0.00 (Mwith = 3.14 ± 0.50 and Mwithout = 3.67 ± 0.69)	t (109) = - 2.84, p = 0.009 (Mwith = 3.16 ± 0.42 and Mwithout = 3.54 ± 0.70)

The influence of other variables

The other variables analyzed were involvement in a didactic activity, chronic disease, marital status, and whether the partner was in the same profession. For these variables, we found no significant differences between obstetrics and gynecology doctors.

Correlational analysis between variables and JSS dimensions

The Spearman correlation was used when at least one of the variables in the correlation was not distributed normally, and Pearson correlation was used when both variables had a normal distribution (tab. V).

TABLE V

The results for the correlational analysis between variables and JSS dimensions

Variables	Payment and promotion	Management and interpersonal relationship	Organization and communication	Overall satisfaction
Age	R = - 0.134 p = 0.16	R = - 0.090 p = 0.34	R = 0.07 p = 0.46	R = - 0.059 p = 0.53
Years of experience	R = - 0.158 p = 0.09	R = - 0.085 p = 0.37	R = 0.09 p = 0.34	R = 0.062 p = 0.51
Children	R = 0.015 p = - 0.87	R = 0.062 p = 0.51	R = 0.075 p = 0.43	R = - 0.071 p = 0.46

Number of working hours/week	**R = - 0.191 p = 0.05***	R = - 0.154 p = 0.11	R = - 0.173 p = 0.07	**R = - 0.22 p = 0.02***
Number of swifts/month	R = - 0.005 p = 0.95	R = 0.018 p = 0.85	R = - 0.018 p = 0.84	R = 0.012 p = 0.90
Extraversion	R = 0.066 p = 0.49	**R = 0.225 p = 0.01***	**R = 0.272 p = 0.00****	**R = 0.222 p = 0.01***
Agreeableness	**R = 0.192 p = 0.04***	**R = 0.268 p = 0.00****	**R = 0.192 p = 0.04***	**R = 0.259 p = 0.00****
Conscientiousness	R = 0.098 p = 0.30	R = 0.116 p = 0.22	R = 0.171 p = 0.07	R = 0.129 p = 0.17
Neuroticism	**R = - 0.408 p = 0.00****	**R = - 0.428 p = 0.00****	**R = - 0.388 p = 0.00****	**R = - 0.458 p = 0.00****
Openness	R = - 0.046 p = 0.63	R = 0.100 p = 0.29	R = 0.169 p = 0.07	R = 0.034 p = 0.72

Among socio-demographic variables, only the number of working hours per week was negatively correlated with payment and promotion and overall satisfaction. Regarding the BFI traits, the statistical analysis identified a positive correlation between:

- agreeableness and all dimensions of JSS
- extraversion and two JSS dimensions (management–interpersonal relationships and organization–communication) and overall satisfaction

A strong negative correlation was identified between neuroticism and all dimensions of JSS.

These results prove that the more hours per week doctors work, the less satisfied they are with payment and promotion and the less overall satisfaction they experience regarding their profession.

The personality traits evaluated with BFI, conscientiousness–openness, had no correlation with the JSS dimensions. Extraversion seems to have no influence on payment–promotion, but it correlated with JSS overall satisfaction, management–interpersonal relationships, and organization–communication dimensions. Therefore, extraverts are more satisfied with interpersonal relationships–communication aspects of their job within their institution. The other trait, agreeableness, was positively correlated with all dimensions of JSS and overall satisfaction, proving that the more compassionate and cooperative a person is the higher level of job satisfaction he/she experiences. Agreeableness is a measure of trust and is helpful to a person's nature.

The correlational analysis proved that personality factors identified with BFI interact with some of the dimensions of job satisfaction and overall satisfaction identified with JSS. To identify which is the most effective prediction model for job satisfaction, we used multiple linear regressions with the hierarchical method (tab. VI).

TABLE VI

Regression analysis

	Models		Payment and Promotion	Management and Interpersonal Relationship	Organization and Communication	Overall Satisfaction
Step 1	Extraversion	R^2adjusted	- 0.002	0.042	0.065	0.040
		ΔR^2	0.007	0.050	0.074	0.049
		F	0.734	**5.841***	**8.770****	**5.677***
Step 2	Extraversion, agreeableness	R^2adjusted	0.002	0.053	0.082	0.062
		ΔR^2	0.013	0.019	0.025	0.030
		F	1.086	**4.090***	**5.960****	**4.657***
Step 3	Extraversion, agreeableness, conscientiousness	R^2adjusted	- 0.007	0.044	0.076	0.054
		ΔR^2	0.001	0.000	0.002	0.001
		F	0.755	**2.702***	**4.035****	**3.110***
Step 4	Extraversion, agreeableness, conscientiousness, neuroticism	R^2adjusted	0.098	0.156	0.139	0.183
		ΔR^2	0.110	0.116	0.069	0.133
		F	**4.004***	**6.120*****	**5.461*****	**7.222*****
Step 5	Extraversion, agreeableness, conscientiousness, neuroticism, openness	R^2adjusted	0.104	0.150	0.132	0.190
		ΔR^2	0.014	0.002	0.002	0.014
		F	**3.567****	**4.908*****	**4.386****	**6.201*****

*** p<0.001, ** p<0.01, * p<0.05

For the payment and promotion dimension, only the last two models of prediction proved to be significant. Of these two, the fourth model, which has extraversion, agreeableness, conscientiousness, and neuroticism as predictors, is providing the most significant contribution, 9.8% of the variance of payment and promotion. Also, among the four predictors of this model, only neuroticism had a significant statistical influence on payment and promotion (p = 0.000), which explains a lot of the variance in the dependent variable, in this case, payment - promotion (b = -0.480, beta = -0.388). The effect of this predictor is a negative one, indicating that the more present this personality trait is, the lower the payment and promotion satisfaction level will be.

For the management and interpersonal relationships factor, all the prediction models were significant. Also, the fourth model, which has extraversion, agreeableness, conscientiousness, and neuroticism as predictors, makes the most significant contribution (15.6% of the variance of management and interpersonal relationships). Of the four predictors of this model, only the personality trait neuroticism had a significant statistical influence (p = 0.000) on the dependent variable management–interpersonal relationships (b = -0.481, beta = -0.399). Its effect was also negative. This suggests that the more present neuroticism is, the less satisfaction a person will experience regarding management–interpersonal relationships.

In the case of organization communication, all the prediction models were statistically significant. The strongest prediction models were the first model with extraversion as a predictor and the fourth with extraversion, agreeableness, conscientiousness, and neuroticism as predictors. Of those two, the fourth had the greatest degree of variance for the dependent variable organization–communication (13.9%). Our results also show that of the four predictors of this model, neuroticism is the only one that has a significant influence (p=0.004) on the organization–communication variable (b = -0.305, beta = -0.307). The effect of this predictor is also a negative one, meaning that the more neuroticism is present in a person's personality structure, the less satisfaction he/she will experience for organization–communication.

Concerning overall job satisfaction, all the prediction models were significant. In this case too, the fourth model with extraversion, agreeableness, conscientiousness, and neuroticism as predictors was the strongest, (18.3% for overall job satisfaction). As with the other variables, only neuroticism had a significant statistical influence (p = 0.000) on overall job satisfaction (b = -0.404, beta = -0.427), its effect being a negative one too meaning that the more neuroticism is present as a personality trait, the less the subject will feel satisfied with professional activities. Based on the results, we can conclude that neuroticism plays the most important role in our participant's personality structure when it comes to predicting job satisfaction.

DISCUSSION

This study confirms some results reported in the literature. Satisfaction about professional life seems to have lower scores for obstetrics and gynecology doctors. Among medical specialties, ob-gyn

physicians obtained the lowest scores for job satisfaction compared with physicians in all other medical specialties (22).

The results prove that 19.64% of subjects are very satisfied or satisfied with their work (overall satisfaction score). Also, considering the domains, 31.25% are satisfied or very satisfied about payment and promotion, 79.46% are satisfied with management and interpersonal relationships, and 52.67% are satisfied or very satisfied with organization and communication. The rate of overall job satisfaction identified by our study is lower than that in other studies: 74 - 80% in USA identified by Leight, Tancredi, and Kravitz (22) and Kravitz et al. (13). One of the reasons could be the fact that no study has been conducted that includes obstetrics and gynecology doctors working in Eastern European countries. The few research studies conducted were in wealthy countries where the professional satisfaction is assured by different factors (income, medical settings, and professional opportunities, among other factors).

The low rate of overall job satisfaction and low level of satisfaction on the subscale related to payment and promotion proven by our research can be explained by two factors: first, the low income of physicians in Romania. This issue is proven by two arguments: the highest rate of "brain drain" among physicians in European Union countries occurs in Romanian physicians (9). The second argument is proven by our research; Romanian physicians have an increased number of working hours per week and a high number of shifts per month, influencing the level of professional exhaustion (33, 34). Secondly, the healthcare policies and Romanian malpractice laws are not encouraging for sustaining professional activity. Most of the medical institutions offer no legal or financial support to physicians in case of a medical error. In this situation, ob-gyn physicians are taking greater precautions when using new methods or procedures involving in risky medical interventions, which is a cause of professional dissatisfaction.

The results for gender differences regarding job satisfaction among doctors are ambiguous in the scientific literature. For example, McMurray et al. (23) found that women are more dissatisfied than men. Leight, Tancredi, and Kravitz (22) found no differences between genders, and Keeton et al (24) found that male obstetricians/gynecologists were less satisfied than women. Our results indicate that women are less satisfied with their job than men are. This fact has an important influence on one of the most important consequences of job dissatisfaction: migration. Statistical data prove that a significantly higher number of female doctors have migrated to Eastern European countries, with some research reporting 80% of the all specialties doctors left Romania to work abroad. In most of the cases, women doctors left together with their children, meaning that the decision to leave was determined to be for the long term or forever (9, 25). In the present study, male doctors were more satisfied than female doctors regarding payment–promotion and organization–communication subscales.

Variables like didactic activity, chronic disease, marital status, and having a partner with the same profession. For these variables, we found no significant differences

between obstetrics and gynecology doctors. The results are different from those reported in the literature; for example, regarding didactic activity, in a study in the US, gynecologists and obstetricians with teaching and research activity obtained higher scores in overall job satisfaction (26).

Among personality traits, agreeableness and neuroticism were proved to impact the most on the level of satisfaction with job and its dimensions. Neuroticism is an indication of emotional instability. Strong negative correlations between neuroticism and all dimensions of job satisfaction proved the importance of this trait in professional life. The results are conforming to some other studies on the influence of neuroticism on professional life. Regarding agreeableness, this personality trait seemed to be more specific to tight and collectivistic societies (27). Considering the history of the country, this personality traits could be explained by the fact that over 40% of ob-gyn physicians experienced for almost half of their lives a collectivistic type of society.

The results are important for ob-gyn physicians and for medical students choosing this specialty. Some comparative studies focusing on medical students revealed that students who enter obstetrics and gynecology score significantly higher on working with people (28). So, more vocational counseling is needed to be provided during their medical studies to help them discover, explain and develop their skills in concordance with their personality traits. Job dissatisfaction will be later in the professional life related to burnout and negative behaviors such as consumption of drugs, malpractice or suicide thoughts (29-31). Making medicals students be aware about the psychological issues of their professional life will help them to better adjust to the professional challenges.

Strengths and limitations of the study

The strengths of the study. Our research included a higher number of physicians from this specialty registered in Romania, compared with other studies (32). So, the results could be generalized. No other study measured the level of satisfaction with job and its relationship with other variables for this medical specialty in an Eastern European country. The results are important for adjusting health-policies for physicians because Romania is the main country with the brain-drain in Europe, high levels of migrations among physicians are registered in the last decade.

The limitations of the study. The research targets physicians working in Romania. The specificity of the ob-gyn profession (rules regarding the working hours per week or the number of shifts per month) is not identical in all countries in the world. For this reason, we cannot say that the results are generally characterizing all physicians in this specialty. The second limitation is due to the number of specialist doctors included in the research and the male/female number of subjects. So, comparative analysis could not be considered generally available for all ob-gyn physicians. Even though the present study provides a lot of valuable information for a better understanding of the psychological factors involved in obtaining job satisfaction, converging results from larger, more generalizable, carefully controlled studies

is needed.

CONCLUSIONS

Based on the study results, the doctors in the study sample experienced a low level of job satisfaction. When it comes to the factors of job satisfaction, physicians were not satisfied with the rewards. Our results highlight the importance of a regular work schedule for doctors because the correlational analysis indicated that the more hours per week the subjects worked, the less satisfied they were about payment and promotions and with their overall work life. Personality traits play an important role in predicting job satisfaction. The presence of depression and insomnia strongly influenced overall job satisfaction.

THE IMPORTANCE OF CLINICAL PREDICTION MODELS IN NON-FATAL PULMONARY EMBOLISM: AN ANALYSIS OF THE BEST KNOWN CLINICAL SCORES (Abstract): The clinical evaluation in pulmonary embolism (PE) is the first instrument used by practitioners in the management of this potentially fatal pathology. The necessity of developing certain valid and especially affordable practical instruments has led to the emergence of various clinical prediction models. The purpose of this paper is to analyze the main clinical scores, as a diagnostic or a prognostic tool, with their strengths and weaknesses. The PESI score, while relatively recent, remains the most investigated and validated prognostic score for the identification of the mortality risk and major adverse events, with economic implications of health services reduction costs through the accurate identification of patients with a low risk who are candidates of early hospital discharge. The simplified Geneva score (with a similar accuracy as the Geneva one) identifies a high or low PE probability, especially in combination with D-dimers, with a prognosis value as well. The Wells and simplified Wells scores identify the high or low probability, being improved by the level of D-dimers, having similar results with the Geneva score. The LR-PED score, conceived as an identification score for low risk, uses biochemical and electrocardiographic markers, but is less validated. The Vienna Prediction Model is another system for the evaluation of the recurrence in which the level of D-dimers is the main prediction factor. Other scores were evaluated with a statistically low significance. The Geneva and the PESI scores remain the most valuable instruments of diagnosis and clinical prognostic, respectively. **Keywords**: PULMONARY EMBOLISM, CLINICAL SCORE, PROGNOSTIC, MORTALITY

Clinical prediction models have become more popular to aid clinical decision-making.

These models were developed to deliver a probability of having (a diagnostic prediction model) or developing (a prognostic prediction model) a certain outcome in an individual.

Pulmonary embolism (PE) is a potentially fatal condition, which's diagnostic and treatment should be rapid, especially in the case of a massive PE. Both the European Society of Cardiology (ESC) guide and the American Heart Association (AHA)

recommends the stratification of patients in patients with a high risk of mortality (massive PE) (1, 2) and patients with non-fatal risk. The non-fatal group comprises 90% of the patients and shows an early mortality risk that varies from less than 1% (low risk) up to 15% (intermediate risk)(1, 2). Using researches dating back as early as the 1990s, but also recent imagistic and laboratory studies, the ESC guide regarding the PE management (2014) recommended that the patients without signs of shock and without increased biomarkers or echocardiographic aspects indicative of right ventricular dysfunction in sPESI score 0 be listed in the low risk group who benefits from early hospital discharge and home care (1). All these are recommendations and not clear indications due to the absence, until recently, of solid proof for selecting patients who may receive outpatient treatment (3). Unlike other diagnostic and prognosis instruments, these clinical scores are based on clinical data which may be applied in any medical unit. Thus, one can determine from the admission, using clinical scores, laboratory and imagistic tests, a profile of the low-risk patient who can receive outpatient care. Taking into consideration the more and more frequent evidence underlining the fact that the low risk subgroup and non-fatal PE benefit from outpatient treatment, British Thoracic Society confirms this recommendation, a measure which may lead to a substantial reduction of healthcare costs (4).

The identification of a valid and easy clinical score to the largest extent possible both from an economic point of view and from the perspective of access to various sophisticated diagnosis instruments, which can be a diagnostic and a prognostic tool at the same time, remains a challenge that this paper attempts to elucidate, by reviewing the main clinical prediction models. Multiple clinical prediction rules were discovered. Some of them, well-known as a diagnostic tool, now have a proved prognostic value, others were defined from the beginning as a prognostic tool. The patients with non-high risk PE can benefit from an accurate and relatively fast clinical examination in order to receive the best possible treatment.

Therapeutic strategies determined by the risk degree and the importance of clinical prediction models. The European PE guide divides patients into 3 risk groups: high, intermediate and low. High-risk patients are those diagnosed with elements of shock or hypotension (defined as systolic blood pressure under 90 mmHg or a decrease of the pressure by more than 40 mmHg in 15 minutes, which is not caused by the debut of an arrhythmia, hypovolemia or sepsis) and who receive thrombolytic therapy and/or hemodynamic and respiratory support (1). They are not covered by the current paper.

Patients with normal blood pressure with non-high risk fall into the intermediate risk group in the presence of dysfunction markers of the right ventricle (RV) (echocardiographic and/or positive BNP) and/or of myocardial lesion (positive I or T troponin). Hemodynamically stable patients without RV dysfunction elements or myocardial lesion show a low mortality risk (<1%). The injectable antigoagulant treatment is administered to all patients when there is a clinical suspicion of acute PE, even prior to the diagnostic confirmation, being followed by oral anticoagulants (1). Thus, the importance of clinical prediction scores is confirmed, as they may identify from the beginning a low mortality risk, the

patients being able to benefit from early discharge and outpatient care, with a direct impact on healthcare costs. Several early discharge criteria may be defined: absence of shock or hypotension, absence of RV dysfunction, absence of important co-morbidities (chronic heart failure, chronic pulmonary diseases, and chronic renal disease), low recurrence risk, exclusion of patent *foramen ovale*, absence of active bleeding and low hemorrhagic risk, absence of the necessity of intravenous analgesic administration and absence of oxygenotherapy indication (3). All of these provided there is a compliant patient who benefits from family support to continue proper treatment at home. But, taking into consideration that patients, not diseases, are treated, each with his/her own particularities, the determination of accurate and statistically well-documented clinical scores is a must. The controversial hypothesis of full treatment outside the hospital of certain well-selected patients has also been tested, provided there is an easy access to a hospital unit. The bleeding, recurrence or mortality risk was similar between the group which received full outpatient treatment and the hospitalized group (5). However, these studies failed to take into consideration less frequent PE complications, such as chronic pulmonary hypertension, arrhythmia or the necessity for inotropic support or thrombolysis, while rare in case of low-risk patients (6). Another argument for the early hospital discharge is the emergence of new oral anticoagulants which do not require laboratory monitoring or adjustment of doses for patients with venous thromboembolism. The potential of the new oral anticoagulants to treat low-risk patients and with early discharge criteria is to be evaluated in future studies. Antithrombotic treatment may have also a potentially beneficial role (7).

Economic impact. Early discharge of correctly evaluated low-risk PE patients is associated with a reduction of hospital costs, allowing the medical unit to use the saved funds for the more efficient and more complex treatment of serious cases. The cost-efficiency ratio of diagnosis and treatment in venous thromboembolism has been evaluated, but especially in deep thrombophlebitis (DVT) which has a similar anticoagulant treatment. A study revealed that the cost of hospital care for a DVT patient was higher for unfractionated heparin as compared to fractionated heparin and the cost of fractionated heparin administration in outpatient treatment decreased by almost a half (8). With regard to PE, it has been proven that the fractionated heparin treatment would be cost-saving if more than 8% would be eligible for early discharge or more than 5% of patients could receive outpatient treatment (9).

DIAGNOSTIC CLINICAL PREDICTION RULES

The Geneva and Wells score. The best known and most used are the Geneva and Wells scores. In a prospective study which comprised 296 PE diagnosed patients admitted at University Hospital of Geneva, followed up for a period of 3 months, six independent mortality predictors were identified as well as other adverse events (PE recurrence, major bleeding). These factors were validated in a study conducted in an emergency department, later to be named the Geneva prediction rule (10). The revised Geneva score comprises 8 variables with a different weight, which might be difficult to memorize and calculate in an emergency unit. The simplified Geneva

score assigns 1 point for each factor used. Low probability is between 0-1 points, intermediate probability between 2-4 points and high probability over 5 points. The accuracy of the diagnosis and the clinical utility are not modified in case of the simplified Geneva score, being able to exclude PE when combined with a normal D-dimers value. The PE prevalence is similar to the original Geneva score and to the Wells score (11). Recently, the Geneva score was investigated in a large study, which evaluated 9 clinical scores as prognostic assessment tools in patients with pulmonary embolism (12). Out of these, the PESI and Geneva scores identified the in-hospital mortality < 1% (low-risk) for the PE patients. The identification of low recurrence risk seems to be superior with PESI score than Geneva score. However, 3 months-mortality was comparable between the 2 scores, both for the low-risk group (1.1% at PESI vs. 0% at Geneva) and for the high risk group (11.1% PESI *vs.* 14.3% Geneva). The use of both scores improves the prognosis evaluation. For instance, the mortality of patients with greater Geneva probability increased from 14.3% to 25% when the high PESI risk was added (13).

The Wells score, published in 2000, is based on a multicenter Canadian study and was developed as a clinical selection pretest of patients with high PE probability. A Wells score higher than 2 is indicative of a high PE probability which requires imagistic explorations, while a score lower than 2 has a negative predictive value for PE of 95% (14). The simplified Wells score assigns 1 point for each variable, a score value higher than 1 suggesting PE probability (15). In the PIOPED II data, the CT positive predictive value for PE at patients with Wells scores lower than 2 was of 58 % indicating that a large portion of the results from these patients are false-positive. The use of D – dimers tests in combination with the Wells score was suggested as a means to help with the patients' selection. It was proved that a negative D-dimers result reduces the PE probability for any Wells score. The PE probability for patients with a score of <2, even with positive D-dimers, was of 7.0 %. This is comparable to the PE rate for patients with a negative CT result (14). The Wells score accurately predicts PE probability at hospitalized patients and this population had a greater PE prevalence than other cohorts. However, the score has no prediction value to exclude a potentially fatal evolution (16).

Given the similarities between the Geneva and the Wells scores, various comparative analyses were conducted. A study that compared 4 clinical scores (the two ones and their simplified versions) concluded that they are similar in their ability to differentiate patients depending on the PE probability and in the patients' proportion who required no imagistic investigation due to the low risk points of the scores with normal D-dimers. Although there were discrepancies at approximately 30% of the patients regarding the low or high probability, there were no differences in the failure rates when the clinic – D-dimers combination was used. The simplified Wells score had similar performances with the Wells score and the revised Geneva score (15).There are limitations, however. The Wells score includes clinical judgment, which is subjective and cannot be standardized (17). It also has no prognostic value. Moreover, it was suggested that the predictive value of this score derives precisely from its subjective component (18).

The Pulmonary Embolism Rule-out Criteria (PERC) rule. This score was obtained to exclude the PE diagnosis using anamnesis and the patient's physical exam. A negative value implies: the clinical judgment of the physician regarding the probability lower than 15% of PE to which the following characteristics are added: age < 50, pulse < 100 beats/min, oxygen saturation > 94% in room air, absence of hemoptysis, absence of estrogen use, no PE antecedents or deep thrombophlebitis, no unilateral edema (objectified by the clinician), no recent surgical interventions or traumas (in the last 4 weeks, which involved endotracheal or spinal anesthesia) (19). Of a greater significance is the fact that this rule applies to a population with a PE prevalence lower than 10%. At this population, the sensitivity was of 100%, the specificity varying between 16-33% with a negative predictive value of 100% (19, 20, 21). In addition, it needs to be applied to low-risk patients, therefore another clinical score, such as the Wells score, should be calculated first. A single study used this score for patients with high risk as well and proved that the PERC is highly sensitive (100%) and has good negative predictive value (20). In case of the population with high PE prevalence, the PERC score, although combined with the revised Geneva score, could not exclude PE without further tests (22).

PROGNOSTIC CLINICAL PREDICTION RULES

The Pulmonary Embolism Prognostic Index (PESI) score. Various comparisons between clinical scores are difficult to interpret but it seems that PESI is the most studied with a total number of 22127 patients. PESI identified 43% of the patients with inter-hospital mortality less than 1%, defined by both guides (ESC and AHA) as low-risk. It comprises 11 clinical parameters with various degrees of prognosis. Depending on the score, the patient falls into one of the 5 classes, with mortality at 30 days ranging from 1.1% to 24.5% (23). Patients in the risk class I or II are low-risk and those in classes III-V are high-risk. However, the original score uses 11 clinical parameters and the final value requires difficult calculations which are hard to make in the clinical practice.

The simplified PESI (sPESI) was developed in 2010 and includes 6 out of the 11 original parameters, dividing patients into high-risk (1-6 points) and low-risk (0 points) patients (24). Both original and simplified PESI were included in the last ESC guidelines on the diagnosis and management of acute pulmonary embolism for risk stratification besides laboratory parameters and imaging tests.

A recent meta-analysis comprising 21 studies has comparatively analyzed the PESI versus sPESI accuracy in predicting adverse events (general mortality and PE related mortality, PE recurrence, non-fatal bleeding)(25). The PESI model also identifies patients with high-risk, a PESI high-risk score is a risk factor for mortality of all causes (AUC 0.78 (95% CI: 0.77 to 0.80)), PE related mortality (AUC 0.82 (95% CI: 0.75 to 0.89)) and significant adverse events. In addition, the sPESI group showed a similar accuracy with the PESI group (similar OR and AUC for PE related mortality, mortality of all causes and significant adverse events) in several studies (25, 26). sPESI was validated in a subsequent study which confirmed its applicability to an independent population (23). This model accurately identifies PE patients who show a low risk of fatal and

non-fatal medical events: no patient from the class I died or showed PE recurrence or major bleeding at 90 days from the initial PE. Out of the class II patients, only 1% died and no patient showed adverse events. The negative predictive value for mortality among patients with low-risk (classes I and II) was of 98-99%. Thus, one can consider in these cases the possibility of early hospital discharge, depending on the patient's particularities (23)

The biological markers of risk in PE are associated with a high risk of fatal events, but one of the most important benefits is their negative predictive value. The association of troponin with PESI score was studied in order to improve the risk evaluation. A study proved the superiority of PESI as compared to troponin I in the identification of low-risk patients. The combined prognosis value PESI + troponin I was not superior to PESI (27). The use of high-sensitive troponin added prognosis value to the PESI score (28). A T troponin ≥ 14pg/ml associated to sPESI ≥1, in case of PE hemodynamically stable patients, was an independent predictor of early death and complications. T troponin < 14 pg/ml and sPESI =0 were identified at 24% of the subjects for whom no adverse effects were mentioned.

Although PESI and sPESI correctly identify low risk, certain patients initially identified as high-risk, after the initiation of the treatment may fall into a lower risk category, using the PESI calculation at 48 hours from the admission (PESI 48). It has been noticed that the decrease of PESI and sPESI at 48 hours after the treatment was associated with the decrease of mortality. Notable modifications were attributed to the improvement of heart frequency, temperature and oxygen saturation. Thus, 8% more patients fell into the low-risk group. Moreover, patients reclassified as high-risk showed a short-term increase of mortality of up to 50%. The modification of PESI and sPESI after 48 hours from the start of the treatment is correlated with subsequent mortality (29). Venetz et al. conducted a comparative study among patients with high and low risk using PESI, sPESI and 30 days mortality (30). Although sPESI accurately identified low risk of adverse events, PESI classified a higher proportion of low-risk patients, having a greater discriminating power than sPESI (6). A recent study has confirmed that the PESI score may also accurately predict long-term mortality (1 year) in case of patients without cancer. sPESI showed a similar accuracy at 3 and 6 months, but significantly lower at 1 year (31).

Compared to the **ESC prognostic model**, the proportion of patients classified as low-risk was smaller. sPESI indentified with more accuracy the low-risk group for whom outpatient treatment may be an option. sPESI is easy to apply, being routinely used in the clinical practice and takes into consideration both the PE severity and the associated co-morbidities without requiring complex laboratory or imagistic tests or other less affordable ones (32).

The **Shock Index** (the ratio between cardiac frequency and systolic blood pressure) is a simple method of predicting high risk of unfavorable events when its value exceeds 1. This value is related to inter-hospital mortality and reveals a negative prognosis in association with echocardiography (33). Analyzed in comparison with the Shock Index, sPESI showed greater prognosis accuracy in predicting 30 days mortality as well as in identifying low-risk patients, having a negative predictive value for death among those with higher risk (34).

The PESI and the Geneva scores are two clinical scores which identify both high risk of adverse events and low risk. PESI had a greater discriminatory power for predicting 30 days mortality than Geneva. Patients with PESI low-risk had a lower mortality and negative predictive value of death than the patients for whom the Geneva score was used (30-day mortality - PESI 0.9%; 95% CI, 0.3 to 2.2; vs. Geneva, 5.6%; 95% CI, 3.6 to 7.6 - $p < 0.0001$) (35). Uresandi et al. developed a prognostic clinical score (**Spanish score**) in a multicenter prospective study at PE patients (36). The score includes the following variables: recent severe bleedings, metastatic cancer, non-metastatic cancer, values of serum creatinine > 2 mg/dL, bed immobilization due to a recent medical condition, absence of surgical interventions in the last two months and age >60. The score classified 47.8% of patients as low-risk. Compared to the Spanish score, sPESI had a better sensitivity and negative predictive value, with a more accurate identification of low risk of adverse events (37). The Spanish score and PESI were formally applied in a randomized control trial aimed to select patients' disposition for the initial treatment of PE. The study was prematurely stopped because of an unexpected high rate of adverse outcomes in included patients at low risk according to Spanish score, even if results were in favor of short hospital stay.(12)

The Low Risk Pulmonary Embolism Decision (LR-PED) rule. This score, recently identified, destined initially to identify eligible patients for early discharge and outpatient treatment, includes: age, preexisting heart failure, atrial fibrillation, heart rate, creatinine, glycemia, troponin I and protein C reactive upon admission. Compared to the sPESI and the Geneva score, it showed a greater sensitivity and negative predictive value for detecting patients with low risk (38). Despite the small dimension of the study lot and the lack of validation in an independent lot which diminishes the clinical applicability, the LR - PED score directs attention on the importance of combining the analysis parameters (troponin I, creatinine, protein C reactive and glycemia) on the heart rate (6).

Vienna Prediction Model is another system for the evaluation of recurrence at patients with PE or idiopathic deep vein thrombosis at the first episode. Age, sex, location of the thrombus, body mass index, V Leiden factor, prothrombin mutation and D-dimers were preselected as relevant risk factors as previously demonstrated. Only sex, thrombus location and D-dimers were identified as relevant predictors of recurrence. It was noticed that the association of the male sex and the localization of the embolism with recurrence risk diminishes in time, while the association with the D-dimers level remains stable. This model allows the prediction of the recurrence risk at various time intervals. Thus, D-dimers were repeatedly measured on a 2 years' duration (39). The repetition of dosing D-dimers after the anticoagulants were stopped was studied before, proving that the persistence of a high level of D-dimers at 3 months from the cessation of the anticoagulant treatment was associated with a higher recurrence rate (40).

The Global Registry of Acute Coronary Events (GRACE) risk score is well-known for high diagnostic performance for adverse outcomes in acute coronary syndrome. Comparisons between GRACE and the other risk scores were performed and it has been shown that this risk score can accurately predict 30-day mortality in pa-

tients admitted for acute PE (41).

CONCLUSIONS

In the daily practice, the existence of scores made up of accessible clinical parameters determines the rapid initiation of optimum therapeutic measures, with the determination of the prognosis and possibly of the outpatient surveillance. The existence of multiple clinical scores may be confusing and time-consuming for a physician, so the large validation of one prediction model (with diagnostic and prognostic value) is required. The Geneva score meets the criteria for both a diagnostic and prognostic clinical rule. In the case of non-fatal PE, which may have sometimes an unpredictable evolution, the PESI and sPESI are the ones to assess the mortality risk and the risk of major adverse events. Certain scores failed to prove their efficiency fully until now, further studies being necessary. The availability of different clinical scores helps doctors to assess PE patients and establish immediate treatment (diagnostic scores) and longtime treatment (prognostic scores) with a favorable impact on the healthcare costs.

THERAPEUTICAL CONSIDERATIONS IN ASSOCIATED ATRIAL FIBRILLATION AND HEART FAILURE (Abstract): Atrial fibrillation is a supraventricular tachyarrhythmia very common in medical practice, often associated with heart failure. Pathophysiological relationship between atrial fibrillation and heart failure is in the attention of numerous case studies, being incomplete elucidated. **Material and methods:** We made a retrospective study on patients with both diseases, hospitalized in Cardiovascular Rehabilitation Hospital, Iasi, during 01.01.2013 - 31.12.2013. The obtained data allowed the classification of patients according to gender distribution, age groups, area of origin, clinical aspects, and association with other diseases, instituted treatment and appreciation of CHADS2 score. Data interpretation was performed with appropriate statistical methods. **Results:** We found a higher frequency of the disease among male patients, male: female ratio being 2:1; the most of the patients lived in urban area. The pick of diseases incidence was in patients over 65 years with a total percentage of 70.84% of cases. We noted that the most common symptoms were exertional dyspnea (in all patients), palpitations, dizziness, headache, fatigue, asthenia, dyspnea at rest and pain / chest pressure. In our study, the majority of patients received the beta-blocker - digoxin combination (46 patients, 40 patients respectively). **Conclusions:** The coexistence of the two disorders could be explained by identifying common risk factors. Beta blockers should be the first therapeutic option in patients with chronic heart failure and atrial fibrillation because they have the effect of controlling heart rate and improve survival in patients with these disorders. Meanwhile, digoxin is a drug, only certain conditions of high accuracy monitoring; whose major clinical indications are heart failure and atrial rhythm disturbances. **Keywords:** ATRIAL FIBRILLATION, HEART FAILURE, DIGOXIN, BETA-BLOCKER

Atrial fibrillation (AF) is a supraventricular tachyarrhythmia very common in medical practice, which consists of a disorganized cardiac electrical activity and progressive deterioration of atrial electromechanical function (1, 2, 3).

Heart failure (HF) is symptomatic in about 30% of patients with AF, and AF is also found in approximately 30-40% of patients with symptoms of HF (4, 5, 6). Pathophysiological relationship between AF and HF was in the spotlight of numer-

ous studies, as it has not been fully elucidated. In patients with chronic HF and AF, beta blockers should be the first therapeutic option because their effect are related to heart rate control and the improvement of survival in patients suffering from these disorders (7, 8). Meanwhile, digoxin is an effective drug, safe only during an accurate monitoring, whose major clinical indications are HF and atrial rhythm disturbances (9, 10). In combination of the two, digoxin has electrophysiological effects which decrease the atrioventricular node level, making it potentially useful in controlling heart rate (11, 12, 13).

MATERIAL AND METHODS

We present a retrospective study on patients with associated pathology - AF an HF that aims to highlight clinical and laboratory aspects, the type of treatment instituted, the occurrence of side effects and the assessment of the CHADS2 score (Cardiac failure-Hypertension-Age- Diabetes-Stroke double), in order to evaluate the risk of stroke and thromboembolism in this class of patients. During 01.01.2013 - 31.12.2013, we recorded a number of 2279 hospitalizations at Rehabilitation Hospital - Cardiovascular Rehabilitation Clinic, Iasi. Within these, 72 were related to the above mentioned pathologies. Our data allowed the classification of patients according to gender distribution, age, area of origin, clinical aspects, association with other diseases, type of instituted treatment and appreciation of CHADS2 score. Data interpretation was performed with appropriate statistical methods.

RESULTS AND DISCUSSION

CHADS2 score. We conducted the evaluation of CHADS2 score in order to assess the risk of ischemic stroke events and thromboembolic phenomena, namely of the need for an anticoagulant therapy, considering the following criteria:

- 2 points for a history of stroke or ischemic transient pathology;
- 1 point for each of the following: age over 75 years, hypertension, diabetes, heart failure.

A score of 0 represents a low risk of stroke or thromboembolism, a score of 1-2 represents a moderate risk and a risk higher than 2 is translated into an increased risk of presenting these complications (fig.1).

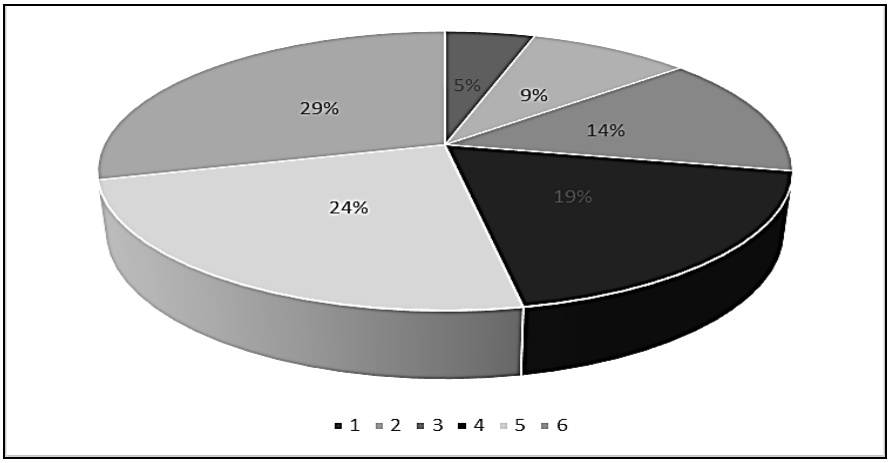

Fig. 1. Distribution of cases according to $CHADS_2$ score;

The distribution by area of origin. The classification of patients based on the area of origin was as follows: urban 54.2%, rural 45.8% (fig. 2).

Distribution of patients by gender. Analyzing the data from figure 3 we can see a higher frequency of the diseases among male patients, male: female ratio being 2:1. In terms of AF, the literature mentiones that men are affected more often than women, and in terms of HF, gender ratio is approximately equal (fig. 3).

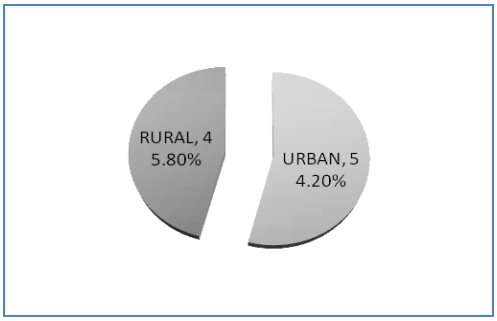

Fig. 2. Distribution of patients by area of origin

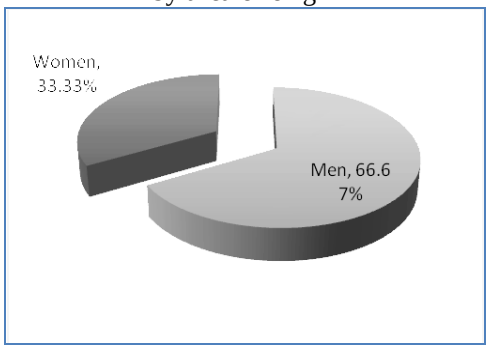

Fig. 3. Distribution of patients by gender

Distribution of cases by age groups. We calculated the mean age of incidence of the associated pathologies that was 69 years. We noted that our results were consistent with the literature data according to which the prevalence increases in patients older than 65 years (14, 15). Indeed, in our study the pick of incidence was in patients over 65 years, with a total percentage of 70.84% of cases, more precisely on the segment 65-75 years being registered the highest percentage of 37.50% of total cases. The lowest age recorded in this study was 53 years, and the highest was 83 years (fig. 4).

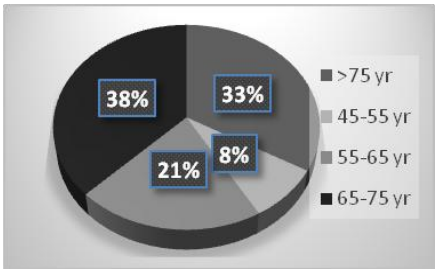

Fig. 4. Distribution of cases by age groups

Family history (HCA). HCA study revealed a number of 27 patients, 12 females and 15 males, who had a first degree relative suffering from heart disease (fig. 5).

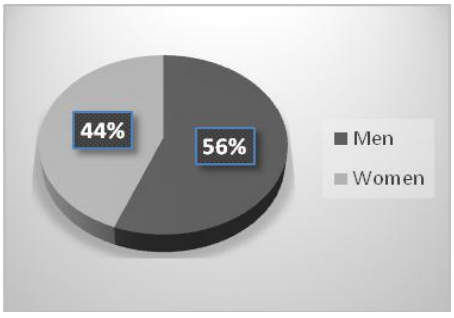

Fig. 5. Distribution of cases by AHC

Risk Factors. Regarding the usual risk factors, we noted a number of 15 patients affected by chronic alcohol consumption, a number of 24 smokers, and 12 who were smokers and affected by chronic alcohol consumption.

Distribution of patients by symptoms. We noted that the most common symptoms are exertional dyspnea (in all patients),

palpitations, dizziness, headache, fatigue, asthenia, rest dyspnea and pain/chest pressure (fig. 6).

Classification of patients according to the type of AF is shown in fig. 7, and according to NYHA class in fig. 8. Associated pathology is also an important element in calculating the risk, in assessing the prognosis of these patients and in choosing an appropriate treatment (fig. 9).

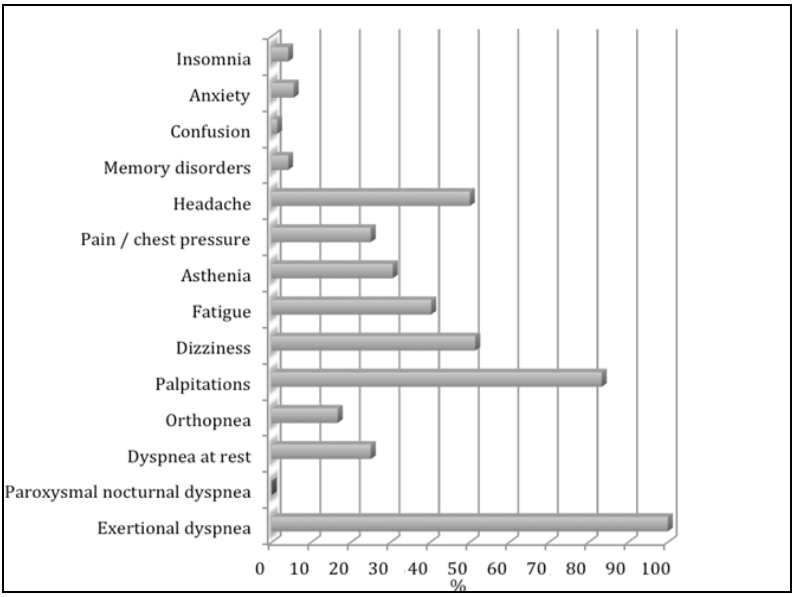

Fig. 6. Dominant symptoms in patients

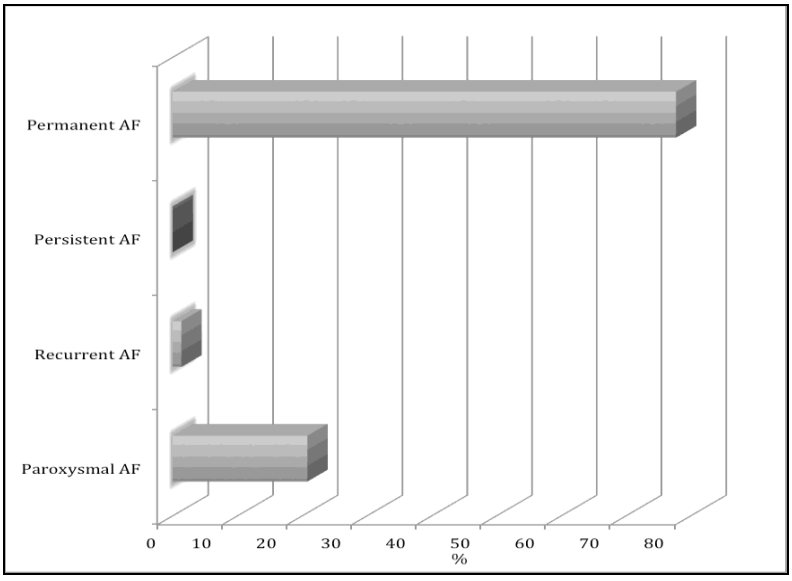

Fig.7. The presence of different forms of AF

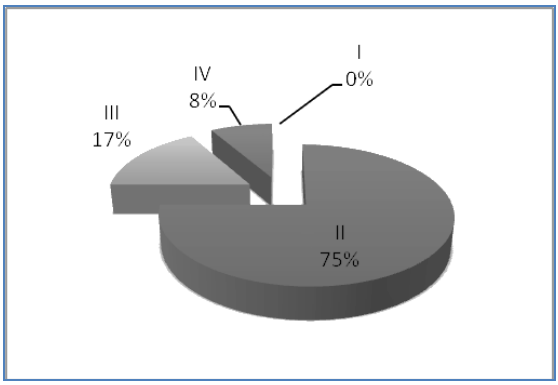

Fig. 8. Distribution of patients according to NYHA class

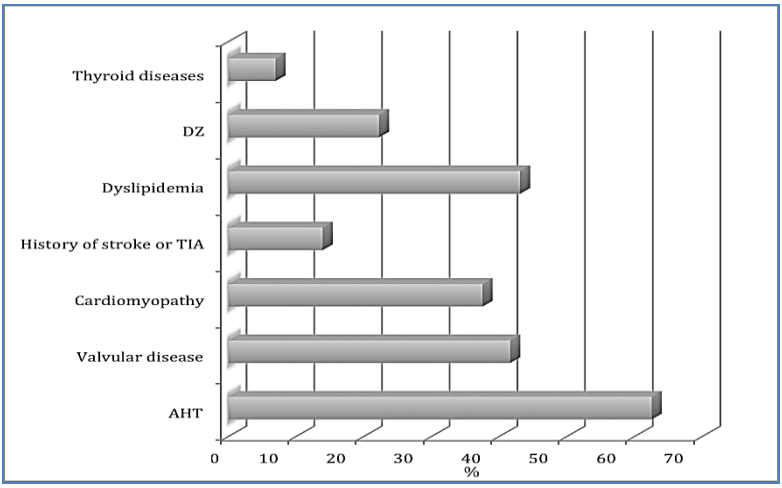

Fig. 9. Distribution of patients according to the associated pathology

The instituted treatment. The classes of drugs that were used for the treatment were diuretics, converting enzyme inhibitors, angiotensin receptor blockers, beta blockers, antiarrhythmics, anticoagulants and antiplatelet agents, nitrates, statins, fibrates and other cardiac preparations. Beta blocker class was represented by carvedilol (22 patients), bisoprolol (14 patients), nebivolol (6 patients), betaxolol (4 patients). Digoxin was administered intermittently 5 days per week, with two-day break, in maintenance doses ranging between 0.25 and 0.50 mg / day, *per os* in a single dose in most patients. Patients over 70 years, those with reduced muscle mass, those with variations in potassium, calcium or magnesium levels, patients with hypothyroidism required caution and special care regarding dose adjustment, more precisely a decrease to 0.125 mg / day to avoid toxic effects. In patients with HF or left ventricular dysfunction involving AF, digoxin can be used as first-line agent for heart rate control. We also know that treatment is made intermittent in patients with NYHA class I, first using other therapeutic classes such as diuretics, while in

those with NYHA class II or III we begin the initial treatment with digoxin, especially in cases with association of the two diseases (16).

We noted that 33 patients had an increased risk of ischemic stroke or thromboembolism, having a CHADS2 score higher than 2; most of them were male patients (18 versus 15). Most of the patients had a score of 2, thus having a moderate risk to develop these complications.

Guidelines ACC/AHA/ESC (American College of Cardiology/American Heart Association/European Society of Cardiology) recommends beta-blockers or non-dihydropyridine calcium blockers as first-line agents for frequency control in AF (17). These agents take action quickly and are effective in reducing heart rate at rest and during exercise in patients with AF. In addition, in AFFIRM study beta-blockers proved to be superior to calcium channel blockers (18, 19).

Studies have shown that beta-blocker carvedilol is effective in these patients, but sometimes we do not get a satisfactory response in heart rate control because of the fact that beta-blocker doses should be higher (20, 21). Digoxin is less effective in controlling ventricular rate compared with beta-blockers in patients with AF, both because it acts slowly, taking about 60 minutes, and because it has a weak action as a blocking agent of atrioventricular node. In addition, it is not effective in controlling heart rate during exercise and can be used only for sedentary patients (22, 23). Combining the two, beta blocker and digoxin, is therefore a solution to get the desired result both in sedentary patients and in those who exercise. In our study, patients received the beta-blocker - digoxin combination (46 patients, 40 patients respectively). We should mention that there were no adverse effects registered during hospitalization.

CONCLUSIONS

Patients who have AF and associated HF are a challenge for the treating physician due to the limitations imposed by their treatment, due to the intricate hemodynamic stress, due to the mechanism of the two diseases, and the unfavorable prognosis of this association. Our epidemiological data showed that patients with this pathology were male, from urban areas, older than 65 years. The major challenges in the treatment of these pathologies are getting sinus rhythm and heart rate control. Beta blockers should be the first therapeutic option in patients with chronic heart failure and atrial fibrillation because they have the effect of controlling heart rate and improve survival in patients with these disorders. Meanwhile, digoxin is a drug, very efficient in conditions of high accuracy monitoring whose major clinical indications are heart failure and atrial rhythm disturbances. In our study, the majority of patients received the beta-blocker - digoxin combination as a solution to get the desired results both in sedentary patients and in those who exercise.

ASSESSING THE RISK OF DECOMPENSATION BY ASCITES AND SPONTANEOUS BACTERIAL PERITONITIS IN CIRRHOSIS

Răzvana Munteanu Dănulescu[1], C.Stanciu[2], Anca Trifan[1]

2. Romanian Academy – Iaşi

ASSESSING THE RISK OF DECOMPENSATION BY ASCITES AND SPONTANEOUS BACTERIAL PERITONITIS IN CIRRHOSIS (Abstract): **Aim**. The current trend is to analyze predictive factors of transition from compensated to decompensated stage by the onset of ascites and later of spontaneous bacterial peritonitis (SBP), which would make possible an early diagnosis of liver cirrhosis at the compensated stage. The aim of the study is to evaluate patients with liver cirrhosis, assessing the rate and the risk factors of decompensation by ascites and SBP. **Material and Methods:** The prospective study included patients with cirrhosis of different etiologies admitted to a ward of the Institute of Gastroenterology and Hepatology of Iaşi in the period 1st January 2010-31st December 2010, which were reassessed clinically and in laboratory for 2 years. The essential criteria for the diagnosis of SBP were the presence of > 250 PMN / mm^3. Compensated cirrhosis was defined as the absence of ascites. The presence of ascites and / or upper gastrointestinal hemorrhage (UGH) marks the state of decompensated cirrhosis. To assess the severity of liver cirrhosis there were used Child-Pugh score and MELD score. Diagnostic paracentesis and ascitic fluid sampling were performed at admission to hospital and during hospitalization, in the event of signs and symptoms of SBP, after antibiotic treatment. Macroscopic, biochemical (albumin, protein), cytological (cellularity) and bacteriological (smear and culture) investigations of the ascetic fluid were performed. Lack of response to empirical treatment was considered in cases of general condition deterioration and decreased PMN <25 % of baseline. **Results:** By comparing the mean values of patients with and without SBP, it is noted that bilirubin and creatinine were significantly higher in patients with SBP, and total protein, albumin and prothrombin time were significantly lower in patients with SBP, these biochemical parameters correlate with the degree of hepatic impairment and may be considered risk factors for SBP. In relation to the mentioned elements, the most important predictors of PBS risk are low protein concentration in ascitic fluid under 1g/dl, increased levels of serum bilirubin and low platelet count. Impaired liver function, infectious complications, and previous episodes of SBP, UGH are risk factors for an episode of SBP. Empirical therapy of nosocomial SBP with third-generation cephalosporins is often inefficient due to the high prevalence of multiresistant (MR) bacteria. **Conclusions:** Assessment of clinically significant portal hypertension (PHT) and the degree of hepatic impairment may stratify patients with cirrhosis according to the risk of decompensation, making possible the identification of high risk patients. The knowledge of the risk factors in SBP is important not only to identify patients who could benefit from preventive therapy, but also in understanding the pathogenesis of the disease.
Keywords: SPONTANEOUS BACTERIAL PERITONITIS, RISK FACTORS, DECOMPENSATION, TREATMENT

The pathogenetic processes involved in cirrhosis are multiple and incompletely understood. Constant cell necrosis and subsequent fibrosis promote regeneration. The evolution towards decompensated cirrhosis is based on clinically significant portal hypertension and the degree of hepatic impairment (1, 2). Multiple studies in the literature have evaluated the predictors of decompensation, the most important being considered porto-hepatic venous gradient over 10 mmHg, MELD score over 10, albumin below 4 g/dL, and low concentration of sodium (3). Child-Pugh and MELD scores can stratify patients according to the severity of liver disease, identifying those in advanced stages of the disease and can also assess their prognosis. The assessment of clinically significant PHT and the degree of hepatic impairment may stratify patients with cirrhosis according to the risk of decompensation, allowing the identification of patients at high risk (4, 5).

Risk factors for decompensation include variceal bleeding, infections, alcohol, drugs, dehydration, and constipation. In addition, obese patients have a high risk of decompensation. In a recent study, decompensation occurred significantly more frequently in obese patients compared with patients who were overweight or who had a normal body mass index (6).

The current trend is to analyze predictor factors of transition from compensated to decompensated stage by the appearance of ascites and later spontaneous bacterial peritonitis (SBP), which would make the diagnosis as early as possible in cases of liver cirrhosis. The aim of the study is to evaluate patients with liver cirrhosis, assessing the rate and the risk factors of decompensation by ascites and SBP.

MATERIAL AND METHODS

The prospective study included 153 patients with cirrhosis of different etiologies admitted to a ward of the Institute of Gastroenterology and Hepatology of Iaşi in the period 1 January 2010-31 December 2010, which were reassessed clinically and in laboratory for 2 years. The essential criteria for the diagnosis of SBP were the presence of > 250 PMN / mm^3. Compensated cirrhosis was defined as the absence of ascites. The presence of ascites and / or upper gastrointestinal hemorrhage (UGH) marks the state of decompensated cirrhosis. To assess the severity of liver cirrhosis there were used Child-Pugh score and MELD score. Diagnostic paracentesis and ascitic fluid sampling were performed at admission to hospital and during hospitalization, in the event of signs and symptoms of SBP, after antibiotic treatment. Macroscopic, biochemical (albumin, protein), cytological (cellularity) and bacteriological (smear and culture) investigations of the ascetic fluid were performed. Lack of response to empirical treatment was considered in cases of general condition deterioration and decreased PMN <25 % of baseline.

RESULTS

Comparison of the frequency with which these complications occurred in patients classified as Baveno and Child (3), revealed significant increase of frequency from each stage of the study, presented in table I.

Risk factors of decompensation with ascites and SBP are analyzed, since the frequency of decompensated cirrhosis increases significantly during the study (fig. 1).

We also studied the evolution of each indicator separately in the three phases of the study (fig. 2, 3, 4, 5).

TABLE I

The frequency of cases according Baveno and Child classifications (phases comparisons)

Compared classes and phases	Phase I		Phase II		Phase III		P
	n	%	N	%	N	%	
Class I Baveno	21	**13.73**	7	*4.58*↓	3	*1.96*↓	**0.0029; 0.0001**

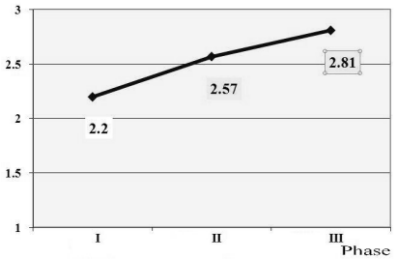

Fig. 3. Evolution of bilirubin

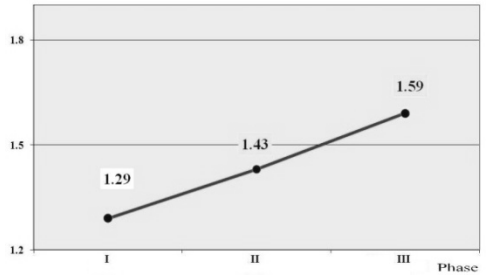

Fig. 4. Evolution of creatinine

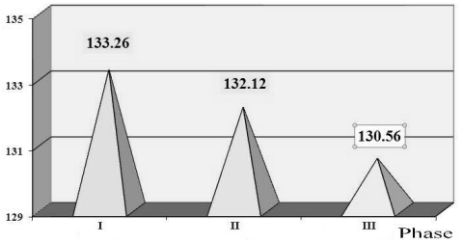

Fig. 5. Evolution of sodium

During the trial there were 58 episodes of SBP in 46 patients, of which 12 were relapses. Of all cases of SBP, 18 had positive cultures, the most common bacteria being Escherichia coli (50% of cases) and Enterococcus faecium (15.66% of cases) (fig. 6).

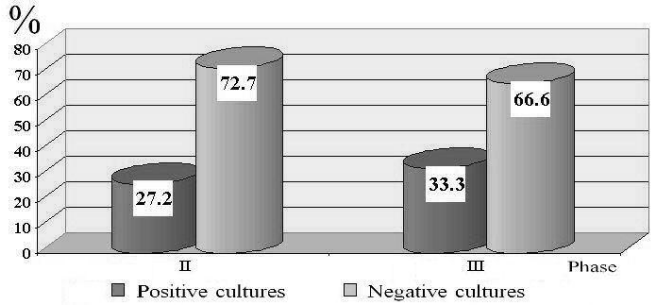

Fig. 6. The frequency of cases with SBP with positive and negative cultures

As shown in the table II, hepatic dysfunction, infectious complications, and previous episodes of SBP, as well as upper gastrointestinal bleeding are risk factors for a new episode of SBP. We compared the biological parameters in patients with and without SBP (tab. III, IV, fig. 7).

Empirical therapy was initiated in all 58 cases of SBP, in 39 cases with cefotaxime and in 19 cases with another antibiotic (Ciprofloxacin or Amoxocilin-clavulanate). Empiric treatment response was achieved in 41 patients, 28 who received treatment with cefotaxime and 12 who had another antibiotic. Treatment failure was recorded in 18 cases. In 7 cases there were isolated bacteria producing extended spectrum beta-lactamases (ESBL), but susceptible to imipenem. Recurrence was noted in 12 cases and mortality was recorded in 9 cases out of 58 patients with SBP. Multivariate analysis identified as predictors of failure of empirical therapy MELD score and SBP caused by bacteria ESBL (tab. V).

TABLE II

Frequency of association of SBP with some complications during hospitalization

Complications during hospitalization (risk factors for SBP)	Total SBP		SBP episode phase II		SBP episode phase III		SBP recurrence	
	N	%	N	%	n	%	N	%
Hepatorenal syndrome	17	36.96	5	22.73	7	29.17	5	41.67
Infectious complications	10	21.74	2	9.10	6	25	2	16.67
Signs of hepatic encephalopathy	4	8.70	2	9.09	2	8.33	0	0
Upper gastrointestinal bleeding	8	17.39	5	22.73	2	8.33	1	8.33
jaundice	8	17.39	2	9.09	4	16.67	2	16.67
Total SBP	46	100	22	100	24	100	12	100

Streptococus aureus	1	0	0	0	0

DISCUSSION

The study included 153 patients; the average age was 60.29 years±10.12 years, with a predominantly urban origin. There was a high prevalence of alcoholic cirrhosis compared with the virus etiology. Numerous studies have focused on the natural history of cirrhosis. To assess the severity of liver cirrhosis there were used Child-Pugh and MELD scores.

Survival statistics highlights the differences between compensated and decompensated cirrhosis (3). According to clinical and biological characteristics of patients on admission, most patients were enrolled in Child C and Child class B.

Results emphasize that most cirrhotic patients are in advanced stages of liver disease.

The current trend is to analyze predictors of transition from compensated to decompensated stage by the appearance of ascites and later SBP, which would make the diagnosis as early as possible in cases of liver cirrhosis and prevent decompensation.

The assessment of clinically significant portal hypertension and the degree of hepatic impairment may stratify patients with cirrhosis according to the risk of decompensation, making possible the identification of high risk patients (7).

After comparing the average values of patients with and those without SBP, it is

noted that bilirubin and creatinine were significantly higher in patients with SBP, and total protein, albumin, and prothrombin time mean values were significantly less in SBP, these biochemical parameters may be regarded as risk factors of SBP.

In relation to the mentioned pathogenic elements, the most important predictors of risk for SBP are low protein concentration in ascitic fluid, under 1g/dl, increased levels of serum bilirubin and low platelet count (8, 9).

The most common bacteria which have been isolated are *E. coli* (50% of cases) and *E. faecium* (15.66 % of cases). Cefotaxime resistance was recorded in 7 cases, ampicillin resistance in 12 cases and ciprofloxacin in 7 cases; mostly identified spread spectrum beta-lactamase producing bacteria (ESBL). Empirical therapy of nosocomial SBP with 3rd generation cephalosporin is often inefficient due to the high prevalence of multiresistant bacteria (9).

Epidemiological differences emphasize the need to know the local epidemiological features and to tailor the antibiotic therapy (10).

CONCLUSIONS

By comparing the mean values of patients with SBP and those without SBP, it has been shown that bilirubin and creatinine were significantly higher in patients with SBP, and total protein, albumin and prothrombin time values were in average significantly lower in patients with SBP, these biochemical parameters correlates with the degree of hepatic impairment and may be considered risk factors for SBP.

In relation to mentioned pathogenic elements, the most important risk factors for SBP are low protein concentration in ascitic fluid, under 1g/dl, increased levels of serum bilirubin and thrombocytopenia.

The therapy with 3rd generation cephalosporin is often inefficient due to the high prevalence of multiresistant bacteria; the epidemiological differences underline the need to be aware of the local epidemiological features and to tailor the antibiotic therapy accordingly.

NEWS

SUBTYPING OF GLIOMAS OF VARIOUS WHO GRADES BY THE APPLICATION OF IMMUNOHISTOCHEMISTRY

Approximately 2% of all adult malignancies are brain tumours, and 80% of these are gliomas. They can occur at any age, regardless of gender or ethnicity. Currently, there is no cure for glioma, and, in spite of aggressive therapy, the morbidity is high. The most aggressive type of glioma, WHO grade IV, is also referred to as glioblastoma multiforme (GBM). According to the cell type, gliomas are divided into astrocytic, oligodendroglial, and ependymal. The neuropathological grading of gliomas is based upon the St Anne/Mayo system, including the assessment of features such as (i) cellular atypia (WHO grade II), (ii) mitotic figures (WHO grade III), (iii) endothelial proliferation, and/or (iv) necrosis (WHO grade IV), all visualized with haematoxylin and eosin (H&E) staining. In 2006, three molecular subtypes of GBM were defined on the basis of molecular profiles and the protein expression of tumour cells, i.e. proneural, proliferative, and mesenchymal. Glioblastoma multiforme (GBM) could be defined by molecular genetic analyses, as well. So, in 2010, independently of the type and grade, GBM were subdivided into four protein-based subtypes by IHC. The four GBM subtypes were classical, proneural, mesenchymal, and neural gliomas. The majority of the low-grade gliomas were of the proneural subtype, i.e. high p53 expression (63% of grade II). The classical subtype, with high EGFR and low p53 expression, was most common in GBMs (39%), followed by the proneural (29%) and mesenchymal (with high CD44 and MERTK expression) (29%) subtypes, a frequency that is in line with previously published data based on molecular genetics. The current strategy for diagnosis of a brain tumour incorporates assessment of the histological type (astrocytic/oligodendrocytic/ependymal) and assessment of the grade (WHO grading system). Recent observations have indicated that the molecular signature of the tumour also appears to be of significance. Assessment of the expression of the five proteins EGFR, CD44, MERTK, p53 and OLIG2 is sufficient for subtyping gliomas, and can be recommended for implementation in clinical practice for both low-grade and high-grade gliomas.(Svetlana N Popova, Michael Bergqvist, Anna Dimberg, et al. Subtyping of gliomas of various WHO grades by the application of immunohistochemistry. *Histopathology* 2014; 64: 365–379)

PARKINSON'S DISEASE AND CAROTID INTIMA-MEDIA THICKNESS (Abstract): Reports about the impact of cerebrovascular disease (CVD) on clinical status in Parkinson's disease (PD) are rather controversial. There have been a few studies and inconsistent results regarding the coincidence of Parkinson's disease (PD) and atherosclerotic diseases, such as cerebrovascular disease. Carotid intima-media thickness (IMT) is a known marker for subclinical atherosclerosis. **Aim:** This study was done to investigate the carotid IMT between PD patients and controls. **Material and methods**: A total of 54 PD patients and 50 controls were examined. The duration of Parkinson's disease, the severity of Parkinson's disease (the Hoehn–Yahr stage) and carotid IMT were examined. **Results:** The mean Hoehn and Yahr stage was 2.78 (range 2-4). Duration of disease had a mean of 7.59 ± 0.85 years. The left CCA mean IMT was 0.900 ± 0.147 in Parkinson group and 0.828 ± 0.118 in control group (p=0.007). The right CCA mean IMT was 0.891 ± 0.176 mm in the Parkinson group and 0.860 ± 0.164 in control group (p=0.360). No relationship between the Hoehn and Yahr stages or the duration of PD with the IMT were found by the Pearson's correlation test. **Conclusions:** The carotid IMT was higher in PD patients than in controls. **Keywords**: CAROTID INTIMA-MEDIA THICKNESS, PARKINSON'S DISEASE, SUBCLINICAL ATHEROSCLEROSIS

Parkinson's disease (PD) is one of the most frequent neurodegenerative disorders, characterized by progressive degeneration not only of the dopaminergic, nigrostriatal system, responsible for the core motor symptoms but also by involvement of many other neuronal systems and organs.There are multifocal neurodegenerative lesions affecting the central, peripheral, and autonomic nervous systems and many other organs (eg, adrenals, retina, heart, skin). The resulting biochemical deficits cause the heterogenous clinical picture including the variegated and often early presenting nonmotor deficit of this multisystem disorder (1). There have been a few studies and inconsistent results regarding the coincidence of Parkinson's disease and atherosclerotic diseases, such as cerebrovascular disease (CVD). Some authors reports that the pathology of vessels supplying the brain contributes to disease severity in PD patients, even without clinically manifest CVD (2). Studies have shown that carotid intima-media thickness (IMT) is an indicator of early generalized atherosclerosis and

that arterial wall thickness is associated with cardiovascular disease and stroke. The carotid IMT can be measured using Doppler ultrasound (3,4). As increased thickness in the intima media complex of the carotid artery has a clinical significance to cardiovascular comorbidity, we examined the hypothesis that patients with PD have an increased thickness of the intima-media complex of the carotid artery (5, 6).

MATERIAL AND METHODS

A prospective, descriptive study was carried out on 54 patients with PD, diagnosed according with United Kingdom Parkinson's Disease Society Brain Bank Diagnostic Criteria for Parkinson's Disease. None of the patients had vascular parkinsonism or was severely impaired by any other comorbidity. Other exclusion criteria were clinical features consistent with a diagnosis of atypical parkinsonism, such as multiple system atrophy, progressive supranuclear palsy, and corticobasal degeneration. The control group was composed of 50 healthy age- and sex-matched subjects. Extracranial carotid IMT measurements were performed according to a predetermined, standardized scanning protocol for the right and left comune carotid arteries. To evaluate carotid atherosclerosis, high-resolution B-mode ultrasonography was performed with a 7.5-MHz linear type probe (Acuson X 300, Siemens, Germany). The IMT was evaluated as the distance between the luminal intimal interface and the medial-adventitial interface, and it was measured using an electronic caliper on the frozen frame of a suitable longitudinal image. Three measurements of far-wall IMT were taken manually in each image using ultrasound calipers, and the average values of these readings were used in the analyses. The mean of left and right IMTs were used in the analyses. Statistical analysis was performed with the SPSS 13.0 statistical package program. Mean IMT of both groups, the duration of PD, and the Hoehn&Yahr scores of both groups were compared. Student's t test and Pearson's correlation analysis were used. Significance levels were set at $p<0.05$ in all cases and 95% confidence intervals (CI) were estimated.

RESULTS

No significant differences in the ages or gender were observed between the two groups. The age of parkinsonian patients ranged between 32 and 85 years with a mean of 66.37±8.90 years while the mean age of controls was a little smaller 63.92±12.63 years. The mean Hoehn and Yahr stage was 2.78 (range 2-4). Duration of disease varied from 1 to 32 years with a mean of 7.59 ± 0.85 years (tab. I**).**

TABLE. I

Demographic data of patients with Parkinson's disease and controls

	Parkinson (n=54)	**Controls (n=50)**	**P**
Age, years	66.37±8.90	63.92±12.63	0.253
Sex, male	61%	56%	0.121
Duration of disease	7.59 ± 0,85		
Hoehn–Yahr stage	2.78±0.79		

Data are mean ± SD or number (%).

Analyses of the left CCA revealed a mean IMT of 0.900 ± 0.147 in Parkinson group and 0.828 ± 0.118 in control group while the right CCA was found to have mean IMT of 0.891 ± 0.176 mm in the Parkinson group and 0.860 ± 0.164 in control group. The difference was statistically significant only for the left side (tab. II, III, fig.1).

TABLE II

Descriptive data of IMT on study groups

Interval	N	Average	Std. Deviation	Std. Error	Confidence interval		Min	Max
					- 95%CI	+95%CI

Correlation of mean values of IMT between study groups

IMT	Control group Mean ± SD	Parkinson group Mean ± SD	*P* value Two-tailed probability
Right	0.860 ± 0.164	0.891 ± 0.176	0.360
Left	0.828 ± 0.118	0.900 ± 0.147	0.007*

*Significant (P<0.05)

No relationship between the Hoehn and Yahr stages or the duration of PD with the IMT were found by the Pearson's correlation test. (tab. IV)

TABLE IV

Pearson's correlation between IMT. duration of disease and Hoehn and Yahr stage

Correlations		Duration of disease	Hoehn Yahr stage
IMTright	Pearson Correlation	-.175	-.015
	Sig. (2-tailed)	.206	.914
	N	54	54
IMTleft	Pearson Correlation	-.144	-.130
	Sig. (2-tailed)	.298	.350
	N	54	54

** Correlation is significant at the 0.01 level (2-tailed).

DISCUSSION

Increased carotid intima-media thickness is a noninvasive marker of systemic atherosclerosis and relates to the risk of future cerebrovascular disease attacks (7).There have been some previous studies of carotid IMT in PD (8.9.10). One reported that the IMT in PD patients was significantly greater than those in controls (4). Others reported that carotid IMT did not correlate with PD duration or severity and others proved that IMT is thinner in parkinsonian patients (2). In our study we founded that IMT is thicker in parkinsonian patients on both carotids arteries but only for the left side statistically significance was reached. We did not find any relationship between Hoehn and Yahr stage and IMT. or between duration of Parkinson disease and IMT of the carotid artery. It is not clear whether increased IMT of the carotid artery is a cause or a result of the severity of Parkinsonism. One possible mechanism by wich subclinical vascular impairment can accelerate the evolution of Parkinson disease is the deleterious effect of otherwise subclinical hypoperfusion on regions made vulnerable by the degenerative process (13.14.15). On the other hand. other mechanisms may link PD with a higher risk of atherosclerosis. L-dopa treatment may promote secondary hyper- homocysteinemia. which may induce atherosclerosis but these hypertrophic changes were observed primarily in patients with a Hoehn-Yahr stage of 3-5 (4). In our study patients were Hoehn-Yahr stage of 2-4 and not all of them had treatment with L-dopa.

CONCLUSIONS

We conclude that patients with PD are at an increased risk for thickening of the intima media of the carotid artery. Due to the small sample size of this study we weren't able to say if this concomitant vascular pathology may contribute to a less favorable course in PD patients. Larger studies are needed to precisely establish the role of vascular factors in PD.

A DIMENSIONAL APPROACH OF SUICIDAL PERSONALITY

Marinela Minodora Manea, Doina Cosman, B. Nemes, H. Coman
University of Medicine and Pharmacy „Iuliu Hatieganu" Cluj-Napoca
Faculty of Medicine
Department of Medical Psychology

A DIMENSIONAL APPROACH OF SUICIDAL PERSONALITY **(**Abstract)**:** Although the last decade research has shown that personality disorders (PD) represent a major risk in suicidal behavior, the role of personality dimensions in determining this type of behavior hasn't been yet studied thoroughly. **Aim:** we intend to highlight some personality traits that may induce a suicidal behavior in patients diagnosed with PD. **Methods**: the sample consisted of 131 patients with PD, 46 of them presenting both a personality disorder and suicide behavior (suicidal ideation/suicide attempt). The personality dimensions were studied using the Temperament and Character Inventory (T.C.I.) developed by Robert Cloninger. Suicide risk was assessed using the Mini-International Neuropsychiatric Interview (M.I.N.I.), Module C - Suicide Ideas. **Results:** although the sample was analyzed in Clusters DSM type A, B, C and an analyze of co morbidities with the Axe I was also made, the analyze was taken further in our attempt to find a common factor that would differentiate the non-suicidal patients from the suicidal ones. The evident result appeared in two character dimensions that are highly related with suicide attempts. **Conclusion**: self-conducting and cooperativeness could be considered marker-dimensions in a quick evaluation of suicide risk. **Keywords**: SUICIDE BEHAVIOUR, PERSONALITY DISORDERS, TEMPERAMENT AND CHARACTER INVENTORY (TCI).

The last decade research has shown that personality disorders (PD) represent a major risk in suicidal behavior (suicidal ideation, suicide attempt, accomplished suicide), as severe as the risk of suicidal behavior manifested in bipolar disorders and schizophrenia (1). Although the non-fatal suicidal behavior including the suicide attempt is one of the criteria for diagnosis in borderline PD and the incidence of the suicide attempts among the persons who meet BP diagnostic criteria is well recognized, the association between the PD or personality traits and suicide hasn't been fully documented. In spite of medicine great progress in studying normal or pathological personality, the role of personality traits or dimensions in determining suicidal behavior hasn't been completely established during the last decades. I would like to mention that Chapter III of the present DSM-V manual introduces modifications in diagnosing PD, namely the dimensional approach in determining a personality disorder as specific trait.

General hypothesis of the research: highlighting some predisposing factors for suicidal behavior in patients with personali-

ty disorders. *Specific hypothesis of the research*: highlighting the particular dimensions of personality in PD patients with suicidal behavior as compared to PD patients without suicidal behavior. Evaluating the relationship between the personality dimensions scores and suicide risk in PD patients.

MATERIAL AND METHODS

In the present research, the *Targeted population* was patients with any PD type. A special interest was given to patients with active suicidality, i.e. patients who have made a suicide attempt a little while before the hospitalization and have manifested an intense suicidal ideation and who were diagnosed with personality disorder. The available population for the present study was the PD patients from a medical center from Cluj (Transylvania central region). The sample consisted of 131 patients diagnosed with PD of any type who solicited medical evaluation and treatment from The Psychiatric Hospital III Cluj-Napoca between 2004-2009 and signed an acknowledged consent.

Selection criteria: patients diagnosed with PD according to DSM-IV-TR (Axe II); age between 18-65 years; patients who signed a consent for participating in this study. Selection criteria of the population included in this study comply with the international methodology and took into account the type of clinical expression (the personality disorder in the present study) and the type of event (the suicidal behavior in the present study) ().

Exclusion criteria: organic personality disorder; mental retard; acute and chronic psychosis.

Comparison groups: *patients with personality disorders and suicidal behavior* (N=46), the suicidal behavior refer to the index episode, i.e. the episode that generates the target symptoms: recent suicidal attempt (cause of hospitalization or presentation of the patient to a clinical consult); present intense suicidal ideation with or without a suicidal plan; present fluctuating suicidal ideation; *patients with personality disorders without suicidal behavior* (N=85).

Work instruments consisted of: The Mini-International Neuropsychiatric Interview (M.I.N.I.) including Module 3/Suicide ideas, Structured Clinical Interview for Axis II Personality Disorders (SCID II) and Temperament and Character Inventory – (TCI) (1, 2, 5).

The categorial tests for evaluating psychopathology and PD were: Mini-International Neuropsychiatric Interview (M.I.N.I.) to identify the co morbid disorders on Axis I and to assess the suicidal risk: low, moderate, high, as in the M.I.N.I. Module C - Suicide ideas; Structured Clinical Interview for Axis II Personality Disorders (SCID II) was applied for the categorial diagnoses of PD on Axis II diagnosis level (1, 2, 5).

Dimensional tests for personality evaluation - The Temperament and Character Inventory (TCI) is a battery of tests under the form of an auto evaluation questionnaire with 240 items of right/wrong possible answers which evaluates 7 high descriptors of personality or behavior, including 4 descriptors of temperament and 3 of character. Each of those descriptors has multiple facets and is composed of several inferior level components (tab. I, II, III).

TABLE I

Descriptors of personality or behavior

The four dimensions of human temperament	The three character dimensions
➢ Novelty seeking ➢ Harm avoidance ➢ Reward dependence ➢ Persistence/perseverance	➢ Self-directedness ➢ Cooperativeness ➢ Self-transcendence

TABLE II

Multifaceted temperament dimensions

ST1	Creative self-forgetfulness *vs.* Conscious individual experience
ST2	Transpersonal identification *vs.* Individual identification
ST3	Spiritual acceptance *vs.* Rational materialism

Quick interpretation of TCI: all types of personality disorders would be characterized by low scores in self-directedness which means low impulse control and low inner force, irresponsibility, deficiency in formulating and pursuing purposes, incapacity to auto help and low self-acceptance. The PD patients also present low cooperativeness manifested in a bad interpersonal functioning, they are intolerants, selfish, hostile, unfriendly, vindictive and time-serving. The more severe personality disorders (e.g. borderline, antisocial PD) show low scores in self-transcendence meaning instability of affects and self-image. *Suicidal behavior analysis - severity of actual suicidal risk* was made using Module 3 - Suicide ideas of Mini-International Neuropsychiatric Interview (M.I.N.I.) thus allowing the classification of patients according to suicidal risk level: low, mild, high (fig.1). *Statistical data analysis* was performed using SPSS 15.0 and the variance analysis (ANOVA) or the Mann-Whitney tests were used for exploring the differences between the comparison groups. Distribution of patients' scores in personality dimensions tests according to suicidal risk categories scored in MINI was analyzed using Tamhane and Turkey SHD post-hoc tests in analysis of variance.

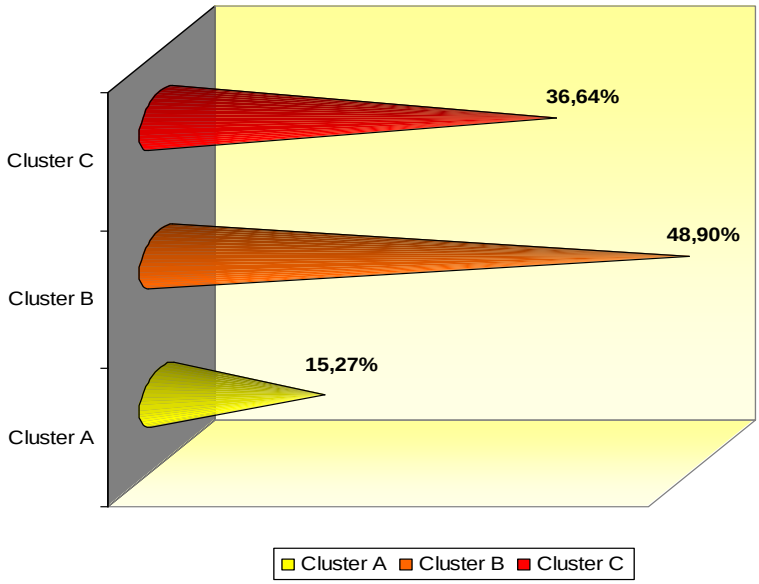

Fig. 1. Suicide risk severity in personality disorder clusters

RESULTS AND DISCUSSION

In our study sample (N=131) the highest percentage of patients belonged to Cluster B DSM -IV-TR personality disorders (48.90%), followed by Cluster C (36.40%). The less represented were the patients with Cluster a personality disorders (36.40 %) (paranoid, schizoid, schizotypal). Cluster B personality disorders is best represented in number and percentage in the analyzed group of personality disorders (N=131) by the increased number of patients with borderline personality disorder (22.14%, practically almost a quarter of the entire lot).

Also we noted a significant presence in the sample group of the narcissistic personality disorders (16.79%). It shall be noted the significant number of cases with obsessive-compulsive personality disorder (19.80 %) that were included after diagnosing with the above mentioned analysis tools (fig. 2).

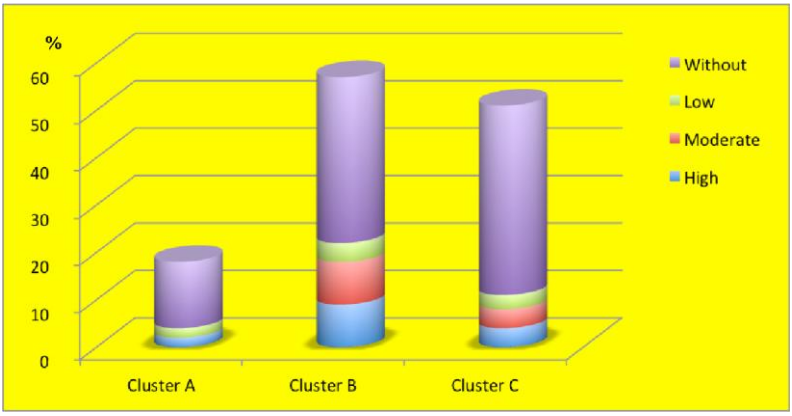

Fig. 2. Discussion of suicidal risk for personality disorder clusters

In our sample the highest percentage was found in Cluster B personality disorders, namely in borderline, narcissistic, histrionic and antisocial patients, in that order of frequency. Distribution of patients in our sample is not surprising, as the incidence rates of personality disorders is worldwide known. Although a more substantial percentage of patients in Cluster A had been preferable, it should be noted that the population of Transylvania by the incidence of personality disorders in the group subjected to observation confirm the existing international epidemiological data. In the present study an increased suicide risk has been reported in cluster B of personality disorders. Clinical evaluation of the borderline patient in a crisis stage is complicated. Those patients often present a history of many autolytic attempts and the impact of a short period of hospitalization on the current suicidal risk is unclear. Chronic suicidal risk in their case is significantly higher than the suicidal risk in general population, because of their history of multiple attempts which increase with self-aggressive behavior (1, 2). Stanley (2) found that patients with a self-mutilation history undergo a risk of suicide because of their increased level of depression, hopelessness, impulsivity and because they are mistakenly perceiving and hence are underestimating the lethality of their suicidal behavior. The chronic risk level can be estimated by a careful case history focused on a previous suicidal behavior and targeted on most severe suicidal attempts considered as such from a medical and intentionality point of view. Evaluation of suicide risk in patients with narcissistic personality disorder is also a unique challenge. Ronningstam and Maltsberger (3) conducted an intellectually provocative description of narcissists undergoing a suicidal risk even when not depressed. The same authors described the possible meanings of suicidal behavior in those patients: attempt to increase self-esteem by feeling in control, trying to protect themselves against anticipated narcissistic threats - "death before

dishonor", act of revenge after a narcissistic trauma, false sense of indestructibility, expressing a desire to attack or destroy an imperfect self. Although we had a small percentage of antisocial personality disorder patients in our sample as the increased suicide risk was found in cluster B patients, those patients require a special discussion, since patients with behavior disorder or antisocial personality present an unparalleled challenge for the clinician. When evaluating them during a crisis, besides the suicidal risk estimation has to be done of the potential risk of violence in those patients particularly. For example, Martine et al. (4) reported that 10 out of 23 patients with antisocial behavior had a history of violent acts on others. We also identified some avoidant and dependent personality disorders in our sample, but in a rather small percentage. Suicidal risk for Cluster C personality disorders in the sample was moderate. Even if cluster C personality disorders were present in our sample those patients had mostly obsessive-compulsive personality disorders, while the presence of Cluster A personality disorders (schizoid, schizotypal, paranoid) was insufficient to produce a statistical difference. I considered being difficult to evaluate the severity of suicidal risk using categorial diagnostic approach as in DSM -IV-TR personality disorder clusters, therefore I favored careful observation of the relationship between personality dimensions of patients and their suicidal behavior (fig. 3).

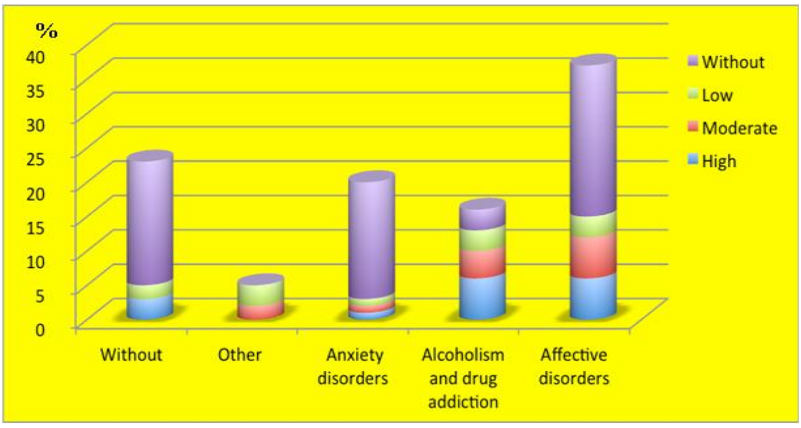

Fig. 3. Severity of suicide risk in PD sample group (N=131), with consideration of the psychic co morbidity type in Axis I

Suicide risk also depends on co morbidity with Axis I disorders and was found to be high in case of mood disorders and addictions - alcoholism and drug addiction. It is well known that a major factor in the escalation of suicide risk level is the presence of Axis I disorders co-occurrent with personality disorders. In our sample group 90% of the patients with personality disorder had co morbid Axis I disorders. Studies on suicidal behavior in personality disorder patients imposed as a necessity an evaluation of Axis I-Axis II co-occurrence. Several authors have identified as a rule the presence of Axis I psychiatric disorders in relation to co morbid Axis II personality disorders (5, 6, 7, and 8). Many studies indicate high prevalence of major depression co morbidity in subjects diagnosed with borderline personality disorder (6, 9,

10, and 11). There is also evidence of addiction co-occurrence within the same personality disorder; the most intensively studied one, i.e. borderline PD (12). In our study suicide risk depended with a high probability on personality disorder co morbidity with Axis I disorders and proved to be higher for affective disorders - major depressive episode and for addictions - alcoholism and drug addiction. Other studies conducted in previous years by the author (in collaboration) identified similar results (13, 14).

In 2002 Hawton (5) stated the lack of studies that explained the escalating suicidal risk phenomenon in PD co-occurrent with Axis I psychiatric disorders. After extended studies on mono- and dizygotic twins, Kendler (15), a recognized specialist in psychiatric genetic research, divided PD in internalized disorders, characterized by latent internalized predisposition, reflected in an internalized experience of suffering as it happens in affective and anxiety disorders and externalized disorders, reflected in an acting-out externalized predisposition as it happens in addictions with psychoactive substances and antisocial behavior. Studies of the same author have shown that personality latent traits are the basis for Axis I disorders and that they remain stable over time and between symptomatic episodes.

Nastase in 2009 cites Markon (16) who in 2005 in an attempt to establish a connection between studies on personality and studies on psychopathology used 52 studies in a meta-analysis and made correlations with scales derived from dimensional personality inventories which included DAPP-BQ, NEO-PI-R and Temperament and Character Inventory (TCI) developed by Cloninger (17). Markon's results lead to a hierarchical model of personality based on superordinate structures called dimensions of personality. Consistent with the idea of hierarchical structure of personality is the opinion of Cloninger (17) who supports the existence of a fundamental multidimensional architecture of psychiatric co morbidity, suggesting that co morbid disorders share common components of vulnerability. Thus, individuals with high scores in avoiding trauma are at increased risk for developing affective and anxiety disorders, that is internalized psychiatric disorders. Individuals with a high level of novelty seeking are at increased risk for drug addiction, suicidal behavior, bulimia, cluster B personality disorders, that is externalized psychiatric disorders. Relationships are rather non-linear (i.e. not one-to-one) with multidimensional configurations of personality traits, presenting multiple alternative completions within Axis I disorders and each and every Axis I syndrome having multiple possible configurations of personality history. Cloninger argues, therefore, that mental disorders are clinically and etiologically heterogeneous being characterized as manifestations of complex adaptive systems described multidimensionally, that these mental disorders have a complex epigenesis implying nonlinear interactions between multiple genetic and environmental influences. While there may be rare cases of discrete disorders with clinical and precise causal limits, those are exceptions. Therefore efforts to describe psychopathology in terms of categories result in extensive co morbidity (17). This would be a possible explanation for the high rate of personality disorders co morbidity with Axis I disorders, as in the present study (87.86 %). As the above mentioned studies highlighted the importance of psychological characteristics and basic multidimensional structures in determining suicidal

behavior stating them as common denominator in suicidal behavior analysis, we chose to make an in-depth analysis by observing and quantifying the personality traits of our patients who presented a high comorbidity with axis I psychiatric disorders such as depression, addictions and anxiety disorders. Therefore, personality dimensional analysis of the patients diagnosed with PD has become a necessity in the present study as category analysis of DSM clusters: A, B, C and the impact of co morbidities in these clusters on the occurrence of suicidal behavior has not brought further clarifications to the research. Cloninger's (17) Temperament and Character Inventory (TCI) was chosen for a dimensional analysis of the patients' personality structures (fig. 4). We decided to use this tool due to the great amount of evidence showing the connection between temperament dimensions and serotonergic, dopaminergic and GABAergic neurotransmitter systems and because we wanted to confirm or deny whether personality or its dimensions are endophenotypes in suicide.

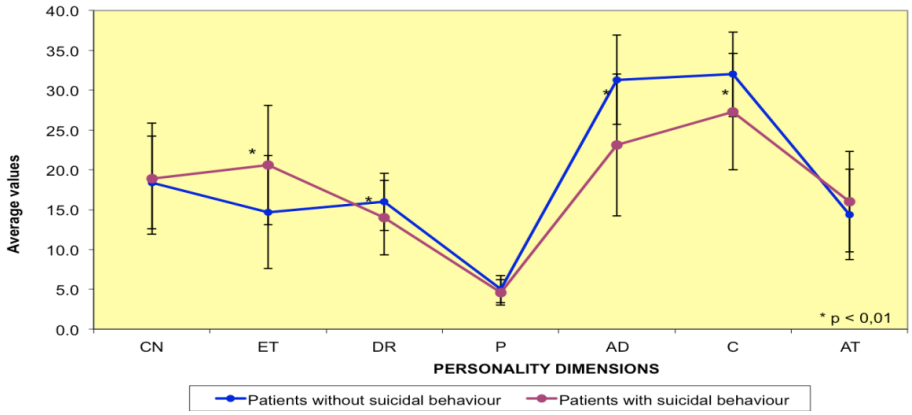

Fig. 4. Differences scored in personality dimensions (temperament and character) Patients with personality disorder and suicidal behavior scored significantly higher in "Harm avoidance" (fig.5) and significantly lower in "Reward dependence" ($p < 0.01$ - ANOVA). They also obtained significantly lower scores in "Self-directedness" and "Cooperativeness" ($p < 0.01$ - ANOVA with Welch correction).

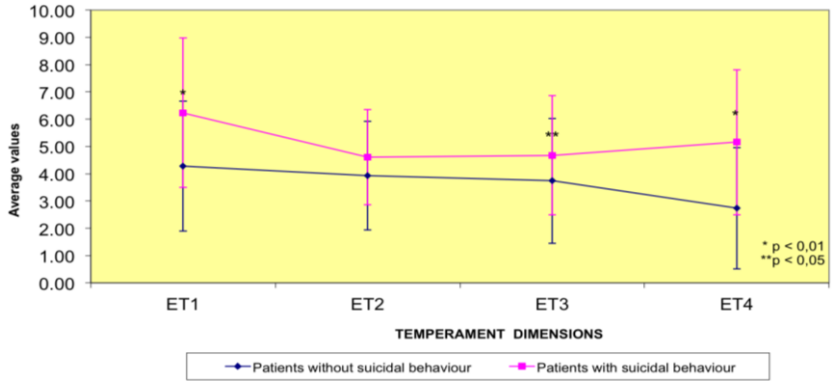

Fig. 5. Differences scored in temperament dimensions (harm avoidance)

Patients with suicidal behavior scored significantly higher in HA1 ($p<0.01$ - ANOVA), HA3 ($p< 0.05$- Mann Whitney U test) and HA4 ($p< 0.01$ - Mann -Whitney U test). Thus, patients diagnosed with PD and suicidal behavior are tensed, apprehensive, insecure, discouraged, pessimistic even when others have no worry, their personality profile is reflected by significantly higher HA1 scores. They also tend to be inhibited and shy in most social contexts, they need encouragement and validation, and they are more sensitive to criticism and punishment than patients with PD without suicidal behavior, as scored in HA3. Patients with suicidal behavior scored significantly low in Self-directedness (SD total) (fig. 6). They obtained significantly low scores in character traits that define this important dimension called self-directedness, namely Responsibility *vs.* Blame (SD1), Purposeful *vs.* Absence of purpose (SD2), Resourcefulness *vs.* Inertia (SD3) and Enlightened second nature *vs.* Bad habits (SD5) as compared with patients without suicidal behavior.

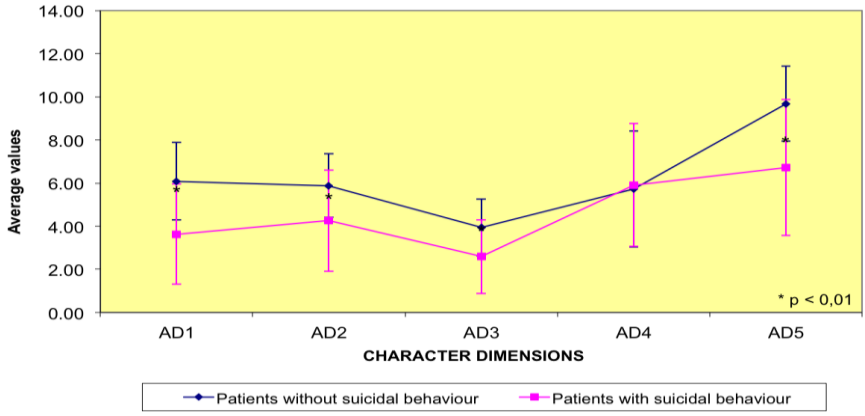

Fig. 6. Differences scored in character dimensions (self-directedness)

Patients with suicidal behavior feel excessively guilty and think that their attitudes, behavior and choices are determined by influences beyond their control and against their will and they do not assume responsibility for their actions as shown by SD1 score. Significantly low SD2 scores reveal their uncertainty about long-term goals and their impulse to respond to immediate needs and present circumstances. Those patients with PD proved unable to delay reward in order to achieve their goal. Moreover, significantly low SD3 (AD) scores mean helplessness, hopelessness, inefficiency. Those individuals have not developed skills and self-confidence for solving problems and thus they feel unable and incompetent to face obstacles. They usually expect others to take the lead and solve problems. Patients with PD and suicidal behavior (suicidal ideation and suicide attempt in the index episode) scored significantly lower in Cooperativeness (total score). They obtained significantly lower scores in those character traits that define Cooperativeness (C1-C5) as compared to the patients with PD without suicidal behavior (fig. 7).

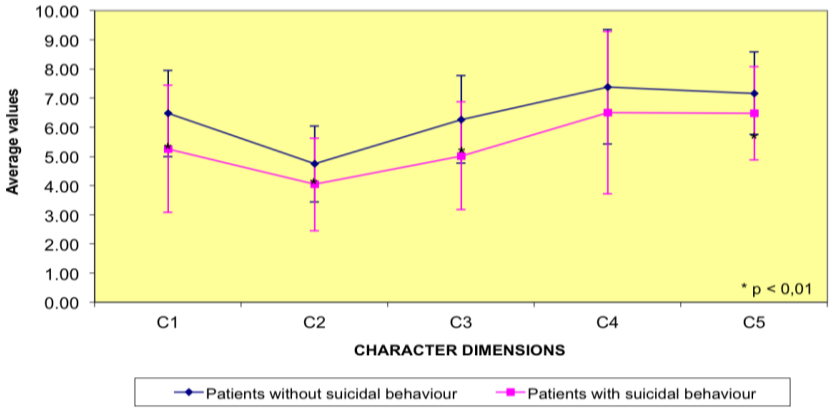

Fig. 7. Differences scored in character dimensions (cooperativeness)

Thus, consistent with significantly low scores in "Social acceptance *vs.* Social intolerance" (C1) suicidal patients are unfriendly and socially intolerant. In our sample group we found they exhibit less patience with others and are judgmental, especially with those who have goals and values other than theirs, as compared to the standard group of patients with personality disorder without suicidal behavior. Statistically significant lower scores at C2, C3 and C5 for suicidal patients portray them as persons with no concern for other people's feelings, unable to sympathize with other people's emotions, sufferings or difficulties, they lack of consistency and honesty in social relations. Those patients are less likely to seek help as they always hide their real suicidal intentions. Therefore, control is no longer effective in case of human individuals with personality disorder because of the low scores in Self-directedness and Cooperativeness which represent the diagnostic specific indicator of a PD. When the control gate disappears, negative emotionality is very high, making human individuals vulnerable to mental disorders that could lead to escalation of suicide risk.

CONCLUSIONS

Suicide risk, according to the present study, has both biological and genetic determinism. This conclusion is supported by validated correlations between increased suicide risk and high, respectively low scores in temperament dimensions: harm avoidance and reward dependence. Social learning has an equal impact on individual's maladaptive behavior, a conclusion supported by intense positive correlations between increased suicide risk and low scores in character dimensions as self-directedness, cooperativeness. Self-directedness and cooperativeness could be considered marker-dimensions for a quick evaluation of suicidal risk, as they are highly correlated with suicide attempt. Dimensional evaluation performed using the Temperament and Character Inventory developed by Robert Cloninger revealed the suicide risk stronger than categorial clinical evaluation, highlighting a high prognostic potential of evaluating suicide risk.

IMPACT OF METABOLIC SYNDROME ON THE DEVELOPMENT OF CARDIOVASCULAR DISEASE (Abstract): In recent years, the metabolic syndrome represents a major health problem worldwide, with a great impact in population, and also at individual level, by an increased prevalence of cardiovascular risk. **Material and methods:** We conducted a descriptive study on a lot of 131 patients hospitalized in Cardiovascular Clinic of Rehabilitation Hospital in Iasi, in the period April 2012 - April 2013. **Results:** In the analyzed group, the largest number of metabolic syndrome cases was recorded in the 50-59 years age group. There were no significant differences between the rural / urban areas ($t = 0.113$, $p = 0.910$). Frequency of ischemia was significantly higher in subjects with essential hypertension of IInd and IIIrd degree (Pearson Chi-square test = 3.955, df = 1, $p < 0.05$). Significant differences were observed on females related to obesity and ischemia, meaning that women with higher obesity are predisposed to ischemic events. Regarding the degree of exercise testing and the origin area, no significant differences were registered (Pearson Chi-square test = 13.526, $p = 0.004$, df = 3). **Conclusions:** Our study offers new information on metabolic syndrome, analyzing epidemiological and clinical criteria. **Key words:** METABOLIC SYNDROME, EPIDEMIOLOGY, CLINICAL CRITERIA.

Metabolic syndrome, also known as X syndrome, insulin resistance syndrome, hypertension syndrome or catecholamine excess syndrome, is an important health problem worldwide by an increased prevalence of cardiovascular risk (1, 2). Clinical identification of the metabolic syndrome is based on the evaluation of specific parameters: hypertension, obesity, glucose, dyslipidemia and hyper-insulinemia, all modifiable beyond those non-modifiable like age and gender (3, 4). The metabolic syndrome seems to increase modestly the cardiovascular risk, whereas in non-diabetic individuals it predicts diabetes much more efficiently. Different studies have compared the performance of the classical cardiovascular evaluation methods (the Framingham risk score, the SCORE charts, the Progetto CUORE score) and metabolic syndrome in cardiovascular disease prediction. At people with high risk the presence of the metabolic syndrome usually does not improve the risk, whereas at people with lower risk its presence increases significantly the chances of cardiovascular disease (5, 6).

MATERIAL AND METHODS

The study included a lot of 131 patients hospitalized in Cardiovascular Clinic of Rehabilitation Hospital Iasi, in the period April 2012- April 2013.

Parameters evaluation

• demographic data: gender, age, residence

• data on lifestyle: smoking, daily physical activity regime

• anthropometric data: weight, height, body mass index, waist circumference

• family and personal history, with particular interest for cardiovascular and metabolic disease: myocardial infarction, stroke, hypertension, type 2 diabetes

• clinical data: blood pressure

• biochemical data: glucose, total cholesterol, HDL-cholesterol, triglycerides

• exercise test

RESULTS AND DISCUSSION

The study group consisted of 59 female patients (20 from 39 patients from rural and urban) and 72 male patients (31 patients from rural and 41 from urban areas). Most cases were registered in the age group 50-59 years with an average of 55.89 (fig. 1). Regarding the distribution by rural/urban area, there were no significant differences ($t = 0.113$, $p = 0.910$) (fig. 2). Also, there were no significant differences related to age and sex.

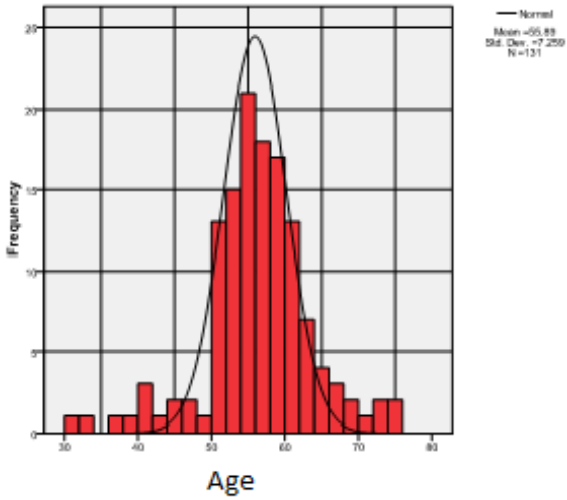

Fig. 1. Distribution by age

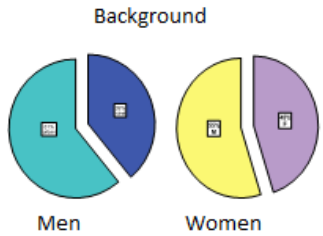

Fig. 2. Distribution by area of origin

A main factor analyzed in the study was the blood pressure. A similar increasing trend was observed in hypertension degree in both females and males, most of hospitalized patients having blood pressure values above maximum. From the statistical point of view, no significant differences were found (fig. 3). An inadequate blood pressure control and poor adherence to treatment remain among the major limitations in the management of hypertensive patients, particularly of those at high risk of cardiovascular events. Many studies have shown that an intensive, protocol-based, management approach to achieving blood pressure control in hypertensive patients in

family practice is effective and works even when there is flexibility built into the algorithm to allow family physicians to use their judgment in individual patients. The results obtained in our study are consistent with results from the literature (7, 8).

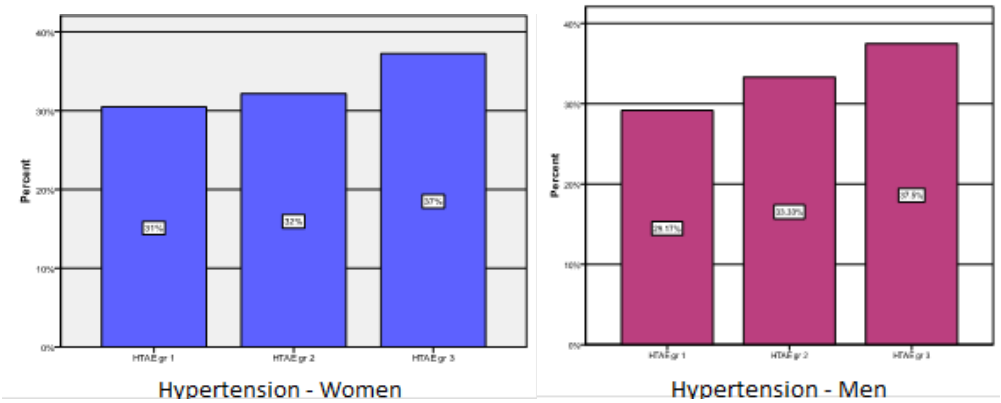

Fig. 3. Sex distribution of hypertension

The literature mentions that area of origin and lifestyles influences the evolution of cardiovascular disease (9). This is found in our study, in urban being more patients with hypertension IIIrd degree, possibly due to stress or poor nutrition. In figure 4, there is a distribution of patients according to the environment, with statistically significant differences between urban / rural (fig. 4).

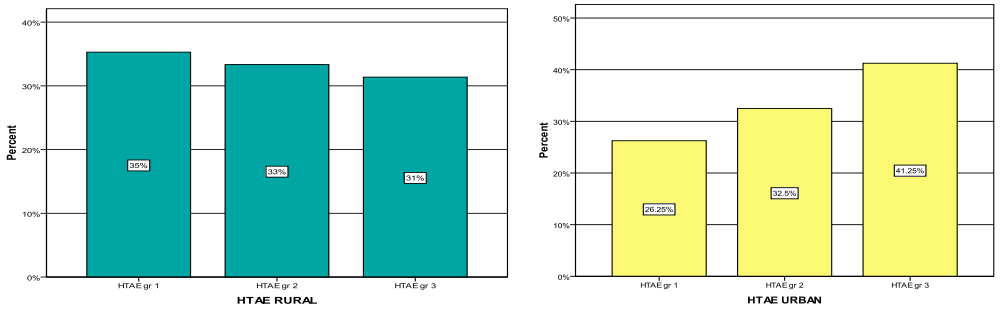

Fig. 4. AHT distribution by grade and area of origin

Although in the graph we observe an increase in positive ischemia frequency from patients with hypertension of I[st] degree to patients with hypertension of IIIrd degree, though not significantly increase in frequency of ischemia for hypertension grade I, II and III was present at individual level. There is a significant difference between ischemia (positive, negative) if we compare the hypertension II and III degree cases together with those with hypertension I degree (Pearson Chi-square test = 3.955, df = 1, p <0.05) (fig. 5, 6). The frequency of ischemia is significantly higher in subjects with hypertension IInd and IIIrd degree, according to data from literature (7, 8).

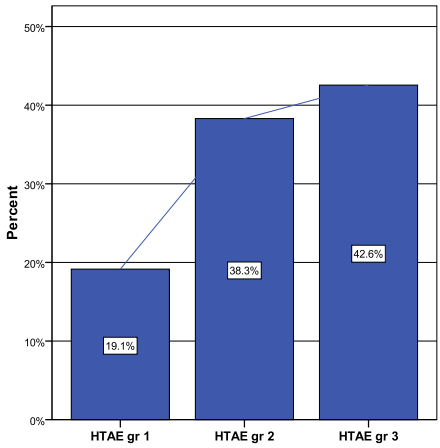

Fig. 5. Hypertension-ischemia relation

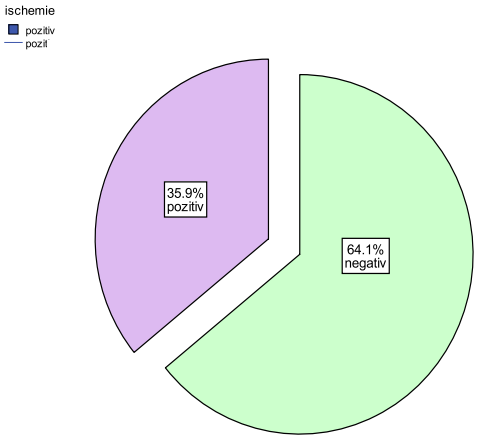

Fig. 6. Graphic representation of ischemia

Comparing the different degrees of obesity and the area of origin there were not significant differences found and no significantly higher risk, but there are significant differences related to sex (Pearson Chi-square test = 14.437, df = 3, p = 0.002, p <0.001). Current researches have shown that the number of obese people is higher in urban areas, possibly due to improper diet and a higher stress (10, 11).

Significant differences were observed for females in relation to obesity and ischemia, meaning that women with obesity have often significantly higher ischemia (fig. 7).There are no significant differences between different degrees of obesity and ischemia, but if we group the overweight and obesity Ist degree in a single category and obesity IInd degree in another category, there are significant differences (Pearson Chi-Square test, p = 0.052). Regardless of gender, the overweight and obesity I degree patients are more likely to develop ischemic phenomena.

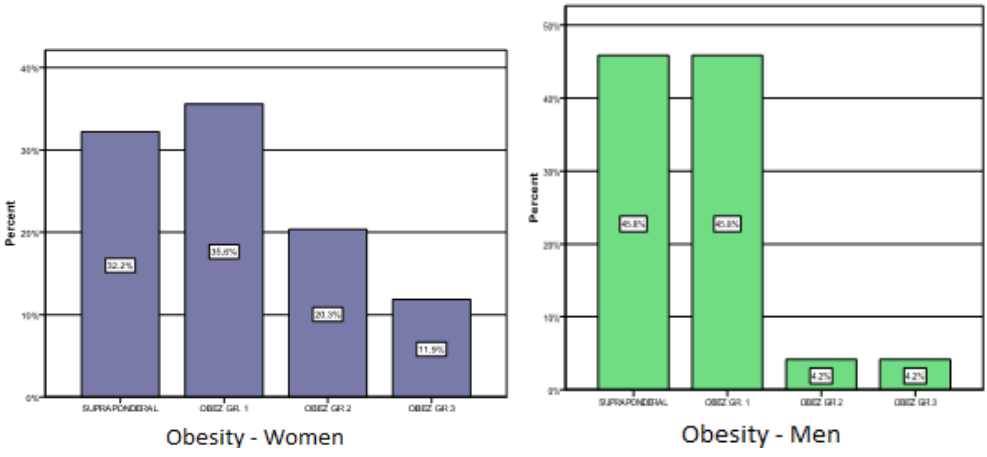

Fig. 7. Obesity-ischemia relation according to gender

Obesity is a consequence of many risk factors, as a reduced physical exercise or increased energy consumption. In the interplay between obesity and metabolic complications are involved many chronic degenerative disorders, including atherosclerosis, commonly associated with hypertension and a chronic low grade inflammation (12).

Numerous observational studies have shown that dietary patterns similar to the Mediterranean diet, rich in fruit and vegetables and high in monounsaturated fats and fiber, resulted in decrease prevalence of the metabolic syndrome (13). Interventional studies also revealed a decrease in markers of inflammation in subjects with metabolic syndrome consuming national dietary guidelines (14).

Another parameter studied was the cholesterol, known as a major risk factor involved in cardiovascular diseases pathogenesis (15). Although the number of patients with dyslipidemia is high, they do not correlate with the presence of ischemia. In our study, there is no significant differences and no significantly higher risk between sex and area of origin in relation to different forms of dyslipidemia (fig. 8).

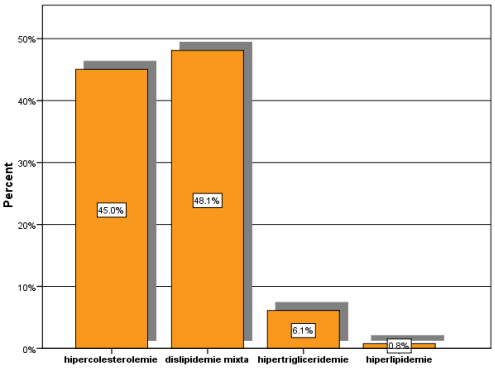

Fig. 8. Dyslipidemia – ischemia relation

Many data suggest that low intensity exercise training, a widely recommended practice, is particularly effective for treating the metabolic, functional and morphological disorders triggered by metabolic syndrome (16). In our study, all patients with metabolic syndrome were tested for effort. The highest percentage of tested patients had submaximal results with statistically significant differences to those with maximal test. Comparing the degree of exercise testing and the area of origin, as well as the sex of the patient, no significant differences were registered (Pearson Chi-square test = 13.526, p = 0.004, df = 3)(fig. 9).

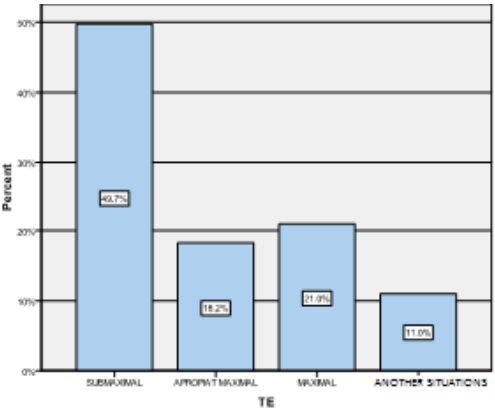

Fig. 9. Exercise testing

Thus, a healthy lifestyle based on a diet low in saturated fat, rich in fruits, vegetables, daily physical activity, no alcohol and no smoking, prevents or slows the metabolic syndrome.

CONCLUSIONS

Our study results provide new information on metabolic syndrome, analyzing epidemiological and clinical criteria. In the studied populational group, the lifestyle modification is the first option of treatment, but in people with high risk drug therapy is necessary. The age group most commonly affected was 50-59 years,

as in the literature. There were no significant differences by age group in relation to sex or area of origin, or between sex and area of origin related to the different degrees of hypertension. Ischemia frequency was significantly higher in subjects with hypertension IInd and IIIrd degree, and reporting various degrees of obesity and the area of origin were not found significant differences and no significantly higher risk, but there are significant differences related to sex, women with high obesity being significantly more susceptible to ischemia.

QUALITY OF LIFE OF PATIENTS WITH ESOPHAGAL REPLACEMENT FOR CONGENITAL AND ACQUIRED ESOPHAGEAL ANOMALIES (Abstract) **Aim:** To assess the long-term quality of life (QoL) and symptoms experienced by patients who underwent esophageal replacement for congenital and acquired children esophageal pathology. **Material and methods:** The study group comprised 71 patients divided into 2 groups, group I: 34 patients who underwent gastric tube esophagoplasty, and group II: 37 patients who underwent colic tube esophagoplasty. QoL score was assessed using a 24-item original questionnaire covering aspects of eating, disease-specific symptoms, physical and psychological development, and social integration. **Results:** QoL scores based on patient and parental responses were very close. Long-term postoperative functional outcomes for the two groups were comparable. **Conclusions:** The QoL scores and general life status were not influenced by the used technique and this pathology should be approached according to the particularity of each case and surgeon's personal experience and preference. **Keywords:** QUALITY OF LIFE, ESOPHAGEAL REPLACEMENT, ESOPHAGEAL ATRESIA, CAUSTIC LESSIONS

The most important criterion for assessing the long-term outcome for patients requiring of pediatric surgical procedures is quality of life (1, 2, 3).

The aim of this paper was to assess the long-term quality of life of a group of patients that have undergone esophagoplasty for congenital or acquired esophageal lesions. The study group comprised 71 patients who underwent esophageal replacement in the Pediatric Surgery and Orthopedics Unit of "Sf. Maria" Emergency Children Hospital, Iasi. The surgical procedures for esophageal replacement in both esophageal atresia and postcaustic esophageal stenosis were: gastric tube esophagoplasty and colic tube esophagoplasty. Since 1992 the authors' procedure of choice for esophageal replacement has been colic tube esophagoplasty (left colon graft vascularized by the left colic artery) because of the lower incidence of complications and the advantages related to this technique. The long-term functional outcome appears to be clinically and radiologically favorable, but the assessment of the quality of life after such a major surgical procedure based on patients and/or their parents perception has not been investigated so far (4, 5).

MATERIAL AND METHODS

The authors have developed an original questionnaire comprising 24 items covering aspects of eating, disease-specific symptoms, psychological and physical status, and level of social integration.

Responses given by the patient/his parents for each item were scored according to the frequency of each symptom occurrence as follows: score 0 – all the time; 1 - most of the time; 2 –sometimes/quite often; 3 – rarely; 4 – never.

The total score of the questionnaire ranged from 0 to 96, with the highest score representing the best quality of life. Depending on the age of the patients at the time of assessment, the questionnaire was completed by them or their parents.

The study population was divided into 2 groups: group I-gastric tube esophagoplasty: 34 cases and group II- colic tube esophagoplasty: 37 cases.

All patients underwent a full investigation protocol with clinical and imaging evaluation (contrast barium study and esophageal-gastric endoscopy) in order to assess the postoperative functional outcome.

RESULTS

The mean time since esophagoplasty was 12.7 years with a range of 8 to 25 years: 14.8 years for group I and 10.9 years for group II.

The mean number of surgical interventions for each case was 4 (group I- 4 surgical procedures/case and group II- 5 surgical procedures/case). The mean age at esophagoplasty was 5.6 years, ranges 2 to 17 years; the mean age of the patients participating in this assessment was 14.1 years, ranges 8 to 37 years.

The social status of the patients was as follows: educational level: primary school 25 patients; secondary school 25 patients; professional school 9 patients; high school 9 patients; post-school qualification 9 patients, and university 4 patients.

Of the adult patients 12 were qualified employees and 14 were doing odds jobs.

The following aspects of eating have been followed: unrestricted diet; size of the meals as compared to other family members; need of water intake during meals; dysphagia; total number of meals per day; episodes of coughing associated with meals.

The questionnaire on the quality of life was completed by the family in 24 cases (patients aged 8 to 13 years) and by the patient in 47 cases (ages between 14 and 37 years).

The mean score of the questionnaire when completed by the patient was 79 (ranges 60 to 90) and when completed by the family was 81 (ranges 70 to 91).

A slightly higher score by 2 points was obtained based on parental perception as compared with patient perception. For the two study groups the mean score was 80 for the gastric tube esophageal replacement (group I), and 81 for the colic tube esophageal replacement (group II).

DISCUSSION

Given the great diversity of treated anomalies, the different ages of patients at the time of surgery, the particularities of each surgical intervention (graft in retrosternal position or in the “bed of the old esophagus”, with or without esophagectomy), an accurate long-term assessment of postoperative outcomes is perfectly justified and opportune (6, 7). The aim of the present paper was to measure and compare some aspects of the quality of life for

patients who underwent colic tube or gastric tube esophageal replacement at pediatric age. As far as the authors are aware, in Romania there are no other studies that have investigated the long- term quality of life in patients with such surgical interventions. As to the functional and imaging outcome, over the time there have been frequent attempts to compare the two used techniques, but all have failed to establish which technique is superior in terms of postoperative results (8,9). In the two groups, the QoL scores were quite similar (80 and 81, respectively) and showed that there were no important patient/parents differences in perception of quality of life in relation with the surgical technique used (1).

Because we did not use a standard questionnaire that could have been applied to healthy individuals as control group, we could not make a comparison of health-related quality of life in our patients with the quality of life in healthy population. We noticed that patients tended to perceive their QoL as being poorer than their parents' perception, and this trend was more marked as adults' age increases and they become aware of the problems related to surgical intervention (1, 2).

CONCLUSIONS

Generally speaking, the patients who underwent esophageal replacement live a normal life although their psychosocial integration and their emotional independence is somehow reduced. The two most frequently used techniques of esophagoplasty have comparable postoperative outcomes in terms of patients/ family perception and socio-professional and emotional integration.

The choice of a specific surgical technique for esophageal replacement in patients with congenital or acquired esophageal lesions should be based on the particularities of each patient because there are no objective criteria to guide the surgeon.

BIOLOGICAL MONITORING AS PROFICIENT ASSESSMENT METHOD IN CHRONIC EXPOSURE TO IRRITATING GASES AND VAPORS (Abstract): Air pollution and its adverse health effect represent a global issue. Long term or permanent exposure at low doses of toxic material may increase the number of new appeared severe respiratory diseases and may aggravate most of the existing chronic cases. **Aim of study**: In the present study, the main toxic aerosols released by the greatest chemical factory in Transylvania were analyzed and their health impacts were measured. **Material and methods:** We have used in our trial biologic monitoring 1786 employees from a chemical factory in a transversal descriptive study. In the same time, we have noticed environmental determination of air quality and also, we have checked the health status and other 90 cases from a nonchemical factory. In this factory there are also pneumotrop harms. **Results** of our study give useful information regarding workers health status, with possibility to make pollution-medical condition association: there was no significant association between occurrence of decreased lung function tests and exposure of chemical irritants compared to the second investigated factory. **Conclusions**: Exposure to pneumotrope hazards imposes safeguards to protect health and biological monitoring has proven absolutely necessary to do so. Last but not least, lifestyle monitoring is to be effective. **Keywords**: IRRITATING GASES AND VAPORS, RESPIRATORY DISEASE, BIOLOGICAL MONITORING.

Fertilizers' production involves a series of chemical reactions such nitrogen capture, nitration, nitratation, during which some intermediate/final chemicals occurs, for example ammonia, nitrogen, nitric acid and others less important. These chemicals are well known to cause mucosal and skin irritation. Also, these chemicals cause irritation of upper and lower airways causing chronic lung diseases (1).

Nitrogen oxides (NOx), especially nitrogen monoxide and nitrogen dioxide which are the "smog's" constituents and give to this a chocolate brown color, also occur in other industrial conditions, like emission gases as result by burning of different fuels; the reaction of nitrogen dioxide with chemicals produced by sunlight leads to the arise of nitric acid, which is a major constituent of acid rain (2). Because of their insolvency in water, NOx tend to not cause immediate upper

respiratory tract irritation. Subsequent respiratory symptoms will be related to the concentration of NOx inhaled, the duration of exposure, the way of exposure and the health of the exposed person (3). Irritation effects already occur after an exposure of 3 ppm, this concentration being able to produce an altered lung test even after a short time exposure, as shown in American studies (1).

Ammonia (NH_3) is produced mainly in fertilizer's industry (about 80%), but also in pigments' industry, plastic and oil industry (4, 5). The ammonia can causes alkaline chemical skin burns, eye burns and lung burns (5). Light exposures affect in the first instance the upper airway, but many severe exposures tend to affect entire respiratory system. The histological damage due to the alkalinity is a liquefaction necrosis with deeper destruction than those produced by an acid. At respiratory tract this leads to cilia and mucosal destruction and finally to lung infections. In addition, secretions, cellular debris, edema and its reaction – smooth muscle contraction causes a significant airway obstruction (6). Airway epithelium may recover within 6 hours after exposure, if the basal layer remains intact. However, the damaged epithelium is often replaced by granular tissue, which is the underlying etiology of chronic lung disease (7, 8). The injuries of respiratory system are proportional to the amplitude of breath, duration of exposure, pH, concentration of gases and liquids (5).

Purpose: monitoring employees for an effective screening, establishing an association between impaired lung tests / chronic lung diseases incidence and professional exposure to irritant vapors and gases, respectively nitrogen oxides and ammonia.

MATERIAL AND METHODS

The study group includes workers exposed to nitrogen oxides and ammonia in a chemical factory. For a long time they had been exposed intermittently to the highest allowed concentration of these irritants (>14 mg/m3 for 8 h-MAC, and >5 mg/m3 for 8 h-MAC (9)) and particles (> 10 mg/m^3). The study group consisted in 1786 workers.

It was performed a professional anamnesis – the 21 items, with special attention at workplace symptomatology, professional age and life conditions / smoking, alcohol, sport, past medical history / especially previous lung diseases. The next stage was to perform function lung tests. The previous stages were studied also in the control group, which consisted in a group of workers from textile industry without chemical respiratory irritant hazards but with the well known organic and inorganic particles exposure, outside of the studied factory. The type of the study is a descriptive transversal study.

RESULTS

Since lower ventilator function test parameters are characteristic to chronic lung diseases with various etiologies we have analyzed the smoking habit of workers as a cofactor in triggering of the specified lung conditions. A number of 53% of the cases were non-smokers. Another important factor in triggering professional lung diseases was the duration of exposure at respiratory hazards (fig. 1).

As shown, over half of employees had more than 15 years at the same workplace. The average is 16.5 years. A number of 48 employees had more than 40 years at the same workplace. A single employee had the highest period: 44 years. It's about a man, non-smoker, with an episode of work-

ing accident in 1972, caused by inhaling a massive concentration of ammonia, but in the present with normal lung function tests.

Interesting is that the average age of employees is 43.6 years, over half of those being over 40.

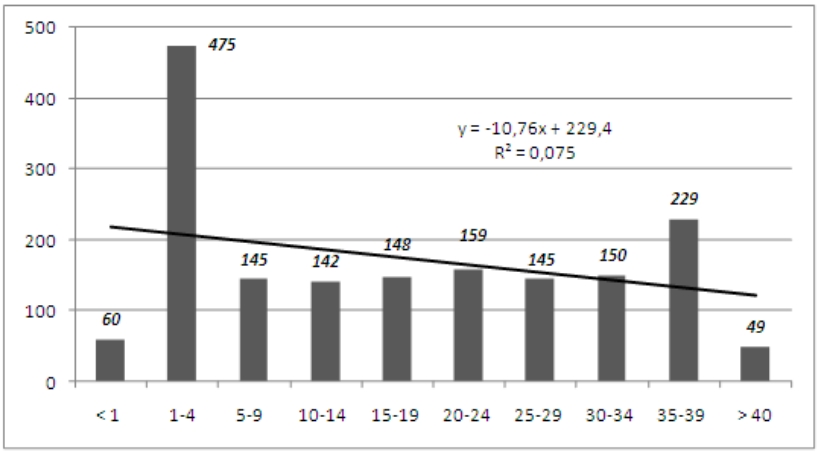

Fig. 1. Total period (years) at present workplace

Since according to the literature, the action of the gases and vapors is to decrease the lung tests parameters, we have performed the cheapest and simplest method – the spirometry, which is also very sensitive to detect a lung disease in its early stage. We have performed this test both in the study group and in the control group (fig. 2, 3, 4).

Surprisingly, a relatively high percentage of workers - almost 70% of the study group, had normal spirometry values, still dominated the obstructive syndromes without decrease FEV1 in 17.34% causes. Because FEV1 value is an accurate indicator of chronic obstructive pulmonary disease, still we wanted fellow it (fig. 3, 4), correlate it with professional history. So we followed up FEV1 according to years of exposure.

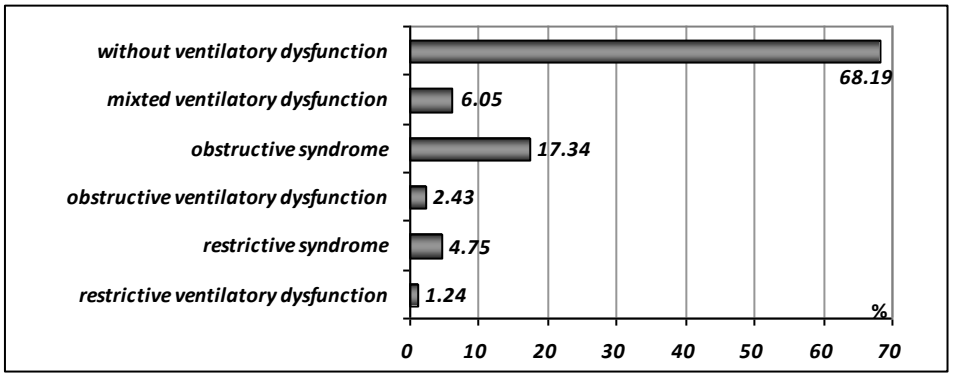

Fig. 2. Functional diagnosis in the study group

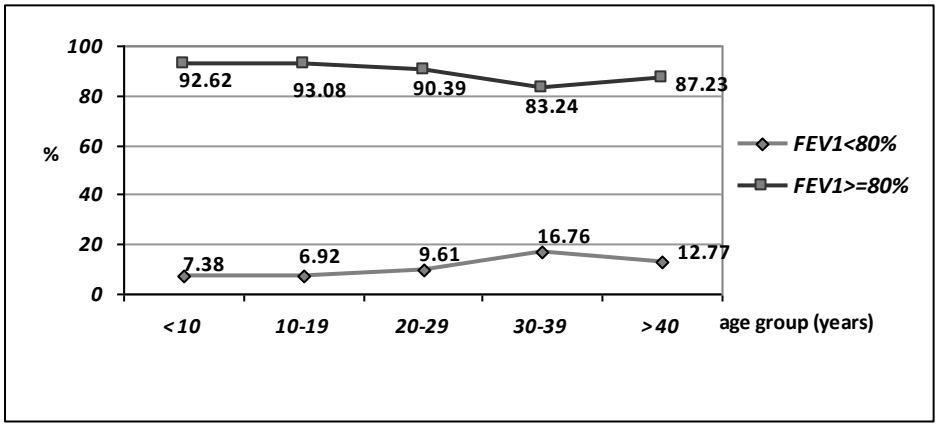

Fig. 3. Evolution of FEV1 values with the years in workplaces

Length professional activity certainly contributed to the decline of FEV1 value. (Correlation coefficient (Spearman r) = -0.06447; 95% confidence interval: -0.1278 to -0.00063; p=0.0415) Than we followed the FEV1 value with workers age (fig. 4).

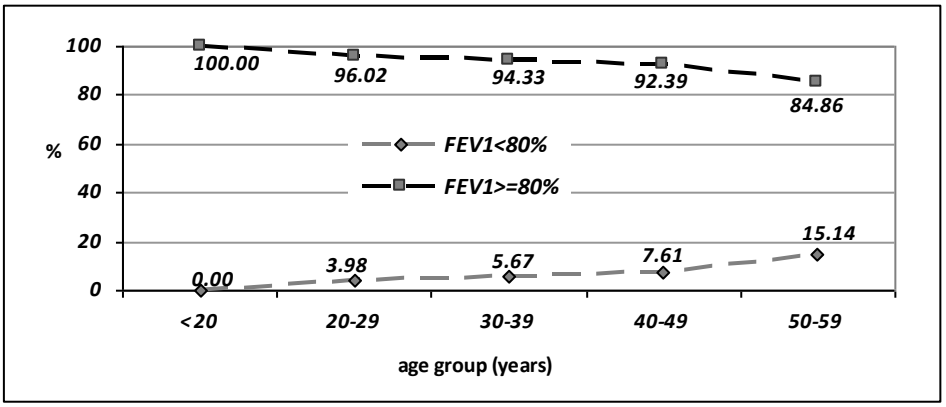

Fig. 4. Evolution of FEV 1 values with the workers ages

Statistically significant negative correlation between FEV1 value and advance in age is evident. Correlation coefficient (Spearman r) = -0.1518; 95% confidence interval: -0.2136 to -0.08874; p<0.0001). Continuing to evaluate data from medical history, and because smoking is a contributory factor in altering the function lung tests we have analyzed functional parameters by this habit (fig. 5).

We founded no significant differences between smokers and non-smokers functional parameters. As the value of FEV1 is a very sensitive parameter, which shows us very confident the different stages of lung obstruction – typical in chronic lung diseases caused by irritant gases and vapors (according to the literature) we have analyzed separately this parameter (fig. 6).

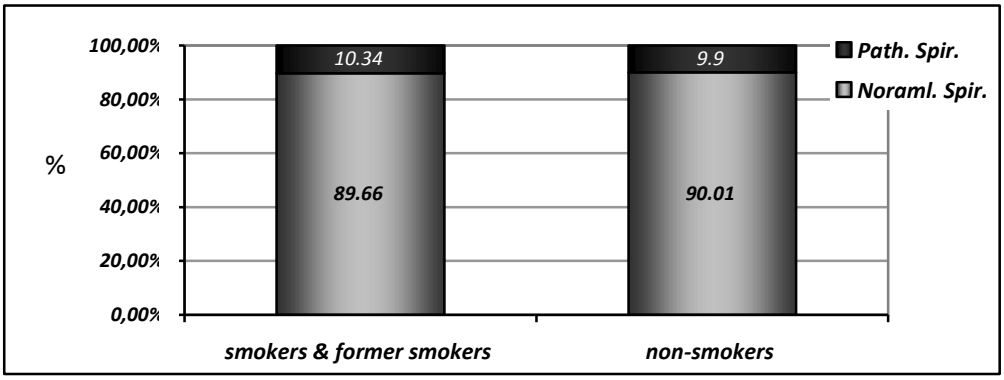

Fig. 5. Smoking habit and spirometry values

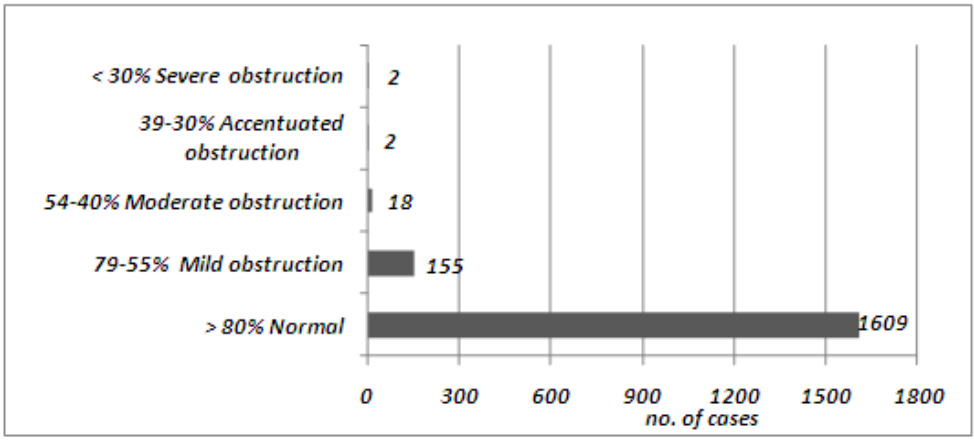

Fig. 6. Severity of FEV1 in the study group

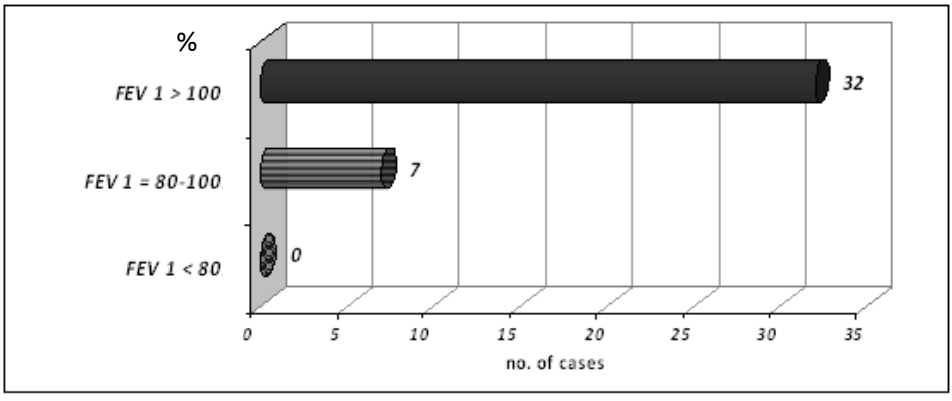

Fig. 7. FEV 1 values in sport practitioner workers

Ventilatory dysfunction grades were mostly mild. Filling in the questionnaires related to their life style, some workers stated sport habits with exercise at least 2-3 times a week. FEV 1 for these workers surprised us: 39 workers had FEV 1 over 100%.

Analyzing overall the chemical platform, especially FEV1 of workers exposed to irritant gases and vapors, according to the FEV1 of the control group with the Fisher test with 95% confidence interval, we have calculated the value of p (tab. I).

TABLE I

Analysis of FEV 1 values in the study group versus the control group

Patients	FEV < 80%	FEV = 80 -100%
STUDY GROUP (exposure to NOx, NH_3, P)	172	1598
CONTROL GROUP (exposure to P)	6	84

The results showed that $p>0.05$, $p=0.4610$; relative risk = 1.458 for 95% confidence interval: 0.6641 to 3.199. That means that there is no significant statistic association between decreased FEV 1 values in the two studied groups.

As a *recommendation*, that it is forbidden for all the workers who have lung infections, even though these are just mild infections to work in an environment with NOx and ammonia, because nasal obstruction, the inability to fell the smell of small amounts of ammonia in the air can lead to dramatic consequences. Even though those with allergic rhinitis or chronic rhinosinusitis. The intoxicated ones can achieve sequels for a lifetime. The workers with previous chronic lung diseases (asthma, COPD, bronchitis) are not allowed to work in such occupational environment.

CONCLUSIONS

We did not find a significant statistical difference between the FEV 1 values between the study group and the control group. The investigated workers have a prolonged exposure to NOx and ammonia in average 16.5 years. 68% of workers had normal values of functional lung tests and the ventilator dysfunctions were mostly mild ones. The age of workers and the years of exposure contribute on diminution of FEV1 and other spirometric parameters.

Smoking habit has not decreased significantly spirometric values among workers with irritating gas exposure. Sport is a good factor for maintaining functional lung tests in normal range (most cases having FEV1 over 100%).

Appealing to biological monitoring of workers in this study, we concluded that there are no significant difference between workers with particles exposure and workers with particles and irritating gases exposure. Biological monitoring of workers in exposure is very important in screening of chronic lung diseases, to diagnose them in time and stop the exposure as soon as possible.

EVODIAMINE - ANTIBACTERIAL AGENT AGAINST DRUG-RESISTANT *KLEBSIELLA PNEUMONIAE*

Nowadays, clinical bacteria are becoming resistant to conventional antibiotics, and multi-drug resistant Gram-negative bacteria confer the greatest risk to public health. The broad spectrum β-lactamase mutations have given rise to extended-spectrum β-lactamases, which hydrolyze oxyimino β-lactams; their emergence is a worldwide public health concern because few antibiotics provide effective anti-extended-spectrum β-lactamases activity. DNA topoisomerases regulate the topological state of DNA that is crucial for initiation and elongation during DNA synthesis. Topoisomerase inhibitors have been developed for antitumor, antiviral, and antibacterial applications. Certain molecules have been reported to enhance DNA cleavage and inhibit relaxation activity of bacterial topoisomerase I, thereby providing antibacterial activity. Evodiamine, an alkaloid isolated from *Evodia rutaecarpa* (Juss.) (Lauraceae), has been reported to exhibit numerous beneficial physiological effects including vasorelaxation, antiobesity, anticancer, and anti-inflammatory effects. The study investigated the bactericidal effect of evodiamine against multidrug-resistant *Klebsiella pneumoniae,* also possessing the extended-spectrum β-lactamases gene type. Evodiamine showed an inhibitory effect against the clinical isolate of *K. Pneumoniae* with a MIC value of 128 μg/mL, significantly lower compared with antibiotics such as cefotaxime, aztreonam, gentamicin, cefazolin, and cefutoxime (> 512 μg/mL). The results suggest that evodiamine acts as a bacterial topoisomerase I inhibitor and it could be used as a potential agent against drug-resistant bacteria (Wu JY, Chang MC, Chen CS, Lin HC, Tsai HP, Yang CC, Yang CH, Lin CM. Topoisomerase I inhibitor evodiamine acts as an antibacterial agent against drug-resistant *Klebsiella pneumoniae. Planta Med* 2013; 79: 27–29).

NUTRITION IN PEDIATRIC INFLAMMATORY BOWEL DISEASE: IS IT USEFUL FOR PREVENTION AND THERAPY?

Daniela Elena Şerban
University of Medicine and Pharmacy „Iuliu Hatieganu" - Cluj-Napoca
Emergency Children's Hospital, Cluj-Napoca
2nd Pediatric Clinic

NUTRITION IN PEDIATRIC INFLAMMATORY BOWEL DISEASE: IS IT USEFUL FOR PREVENTION AND THERAPY? (Abstract): Countless studies aiming to discover the cause and cure of inflammatory bowel disease (IBD) have been conducted over the years worldwide. Food nutrients were believed to play a certain role in the causation of the disease, in conjunction with genetic, immunologic, environmental and other factors (especially intestinal microbiota). Various nutrients were found to be involved, sometimes with controversial results, possibly pertaining to geographic regions. Nutrition has to be especially considered in children as disease itself and/or the medication can severely impair normal growth and development, sometimes with permanent long-term sequels. We reviewed the data on the possible roles of diet in preventing the disease and relapses. We emphasize the crucial importance of enteral nutrition in inducing and maintaining the remission of Crohn's disease, according to the existing consensuses (benefits, indications, routes of administration, types of formula, duration, results). We also present data on parenteral nutrition in pediatric IBD, with current updates from literature. **Keywords:** NUTRITION, CROHN'S DISEASE, THERAPY, CHILDREN

Despite numerous studies performed worldwide, the etiopathogenesis of inflammatory bowel disease (IBD) remains largely unknown. It is considered to be the result of the interactions between genetic, immunologic and environmental factors, closely related to intestinal microbiota. The role of various food nutrients in favoring IBD has been extensively studied over the years. Possible mechanisms include direct effect of dietary antigens, alteration of gene expression, alteration in the composition of the enteric microflora, and the effect on gastrointestinal permeability (1). Nutrition has to be considered especially in children, also since the disease itself and/or the medication (including steroids) could severely impair normal growth and development, sometimes with definitive long-term sequels.

Undernutrition and particularly growth failure are less common in children with ulcerative colitis (UC) compared to those with Crohn's disease (CD) (2). These aspects should be especially considered, since 20% of IBD cases occur before the age of 18 years (3). While in adults therapy aims especially at inducing and maintaining remission (ideally with mucosal healing), in children, recovery of nutritional deficiencies and restoring the somatic and psychological development need to be also

considered (4).

Nutrition in IBD refers to: enteral nutrition (elemental, semielemental and polymeric liquid formulas), parenteral nutrition, and diet (both during the flares and remissions). The new ECCO guidelines in 2010 (3) and especially NASPGHAN in 2012 (5) have brought important specifications regarding enteral nutrition in CD.

Are any food components directly involved in IBD etiology?

Many nutrients have been considered in various studies, sometimes with controversial results, possibly pertaining to geographic regions. In a recent Italian study, high cheese intake was associated with CD and that of pasta, sweets, butter, and margarine with IBD. Conversely, high fish and potato intake significantly reduced the risk of IBD, vegetables and tuna reduced the risk of CD and eggs decreased the risk for UC (6). In a recent Danish research, low fiber diet and high sugar intake were significantly associated with development of IBD (7). In a recent systematic review of previous studies in adults, published in March 2012, it was shown that a diet high in protein from meat and fish has been associated with a higher risk of IBD. Intake of n-6 polyunsaturated fatty linoleic acid (from red meat and some cooking oils and margarine) may confer a risk for UC, whereas n-3 polyunsaturated fatty acids may be protective. No effect has been found in intake of dietary fibers, sugar, macronutrients, vitamin C, D, E, carotene, or retinol on risk of UC (8). A comprehensive analysis of possible roles and mechanisms of dietary components in determining IBD has been recently published. It has been shown that there could exist some ‘‘proinflammatory’’ eating habits in genetically susceptible individuals, playing a role in IBD. However, *there is currently insufficient evidence to support a direct relationship between diet and IBD (1),* larger prospective studies being required, including young subjects.

Recently, the role of hypovitaminosis D (with connotations in food intake) in determining IBD (especially CD) has been pointed out (9); higher predicted plasma levels of 25(OH)D significantly reduce the risk for incident CD and insignificantly reduce the risk for UC in women (10).

What is the nutritional status of children with IBD?

Undernutrition and especially growth retardation are more often encountered in CD than in UC. A body mass index (BMI) < 5th percentile at the diagnosis was seen in 22-24% of children with CD, compared with UC - 7-9% (2). At the time of diagnosis, up to 85% of children with CD and 65% of those with UC have weight loss (11). In the 2nd Pediatric Clinic in Cluj-Napoca (1998-2010), all children with CD had weight loss until the diagnosis, compared with 74.1% with UC (average of 4.8 kg and 3 kg, respectively). Height deficit at presentation has been found in 46% of children with CD (12). Decreased height velocity is the most sensitive parameter of an impaired linear growth (could appear years before the symptoms) (13) and has been detected in about half of children with CD (12). Despite the therapy, a quarter of children with CD may not achieve full adult height potential (12). Conversely, children with UC (without excessive steroid use) reach their expected adult height (13). Moreover, children with IBD (especially BC) are particularly prone to disturbed bone health (due to the disease itself and/or steroids) and severe osteopenia is detected in 12-18% of those with CD *vs.* 3-6% in UC (14).

On the other hand, recent studies carried out in US have shown that overweight/obesity does exist in children with IBD. In 783 children with newly diagnosed IBD, a BMI consistent with overweight or risk for overweight was present in 10% of those with CD and 20-30% with UC (2). In other study on 1598 children, the prevalence of overweight/obese status was 20% for CD and 30% for UC (15).

The etiopathogenesis of undernutrition is multifactorial. Increased digestive losses (diarrhea, bleeding, protein-losing enteropathy), increased requirements, and malabsorption (due to inflammation, fistulas, resections) can be responsible, but the most important factor is the suboptimal food intake, secondary to anorexia (due to pro-inflammatory cytokines and adipokines, alterations in hypothalamic serotonin levels), symptoms, diet and medication (Rev. in 11,16). Malnutrition, pubertal delay, steroid therapy and pro-inflammatory cytokines (by direct effect on bone metabolism, promoting anorexia and interference with growth hormone/insulin-like growth factor-1 axis) contribute at the growth failure (11, 16).

It is beyond the aim of this paper to detail the methods of assessing the nutritional status. We only highlight the importance of assessing (both at the diagnosis and after, every 3-6 months) the following items: weight, height, BMI and the pubertal Tanner staging. Bone mineral status should be assessed using dual-energy X-ray absorptiometry (4, 16). Consequently, the therapy could be adjusted to provide a normal growth and development.

WHAT IS THE ROLE OF NUTRITION IN IBD?

Since there is yet no cure for IBD, there is only pathogenetic therapy, the following methods being used (sometimes in combination): medication, surgery, nutrition and psychotherapy. A successful program based on nutrition requires, besides the pediatric gastroenterologist, a dietician, a dedicated nutrition nurse, a psychologist and, especially, financial support (5).

1. ENTERAL NUTRITION (EN)

EN refers to the administration of liquid formulas, containing the nutrients necessary for growth and development, providing also a high caloric intake. The differentiation between the types of formulas is made by the degree of protein hydrolysis. Accordingly, there are polymeric (whole proteins), semielemental (oligopeptides) and elemental (only amino acids) formulas. EN can be exclusive (EEN), as the sole dietary source and partial (PEN), in addition to a normal diet (5).

1.a. EEN is considered the *first-line therapy in induction the remission in children with CD* (3, 4, 11, 17), however it is not effective and should not be used in UC (4). EEN has many important *advantages:* bowel rest, modification of the gut flora, decrease of the antigenic load to the gut, reduction of the intestinal inflammation with mucosal healing, down-regulation of the pro-inflammatory cytokines, normalization of the biological inflammatory markers, improvement of growth, nutritional status and of bone health, as well as of the quality of life, with minimal adverse effects (3, 11, 17, 18, 19). *Disadvantages* concern especially the difficulties in compliance and the high costs (5, 11, 17). The *duration* of the EEN is usually 6-8 weeks, however increasing the interval until 12 weeks could have additional benefits (5). *Remission* through EEN appears in up to 85% of chil-

dren, being as effective as steroids in the most recent meta-analysis on 204 children (3,17,20), but without the adverse effects of steroids. Contrary to previous opinions, EEN is effective *irrespective of the enteral or colonic locations* of the disease, being recommended also in those with *perianal* involvement, according to the recent consensuses (3, 5, 17, 21, 22). When choosing the type of formula, we have to consider that very recent studies have shown that *polymeric formula* is not inferior to the elemental or semielemental ones (3, 4, 5, 23, 24), being used in more than 90% of centers in Europe, North America and Pacific Asia (17). Among the advantages of the polymeric formula, better weight gain (25), better taste and lesser cost have to be mentioned (5). In the 2nd Pediatric Clinic in Cluj-Napoca, as in many other gastroenterology centers across the world, we have used Modulen IBD®, containing TGF-β (transforming-growth factor β), with many functions: anti-inflammatory activity, growth improvement, regulation of immune response and tissue repair. As regards the *route of administration* – oral, nasogastric tube or gastrostomy, obviously the oral route is preferred, whenever possible, with better compliance (4). A recent study at Necker Hospital in Paris, on 106 newly-diagnosed children with CD using EEN with Modulen IBD® for 8 weeks, showed that fractioned oral feeding is as effective as the continuous enteral feeding to induce remission (75 *vs.*. 85%, respectively), with similar compliance rates (87 *vs.*. 90%, respectively) (26). *The estimated energy requirement* can be calculated using the Schofield equation (27), considered the best instrument (28); other factors (related to activity, fever) could be added (5); most children need approximately 120% of reference nutrient intake (4, 5). Quantities should be introduced gradually, over 3-6 days, until the full volume is reached (5). *Time to remission* has been reported between 11 days and 2.5 weeks (20); however, 3-4 weeks have to be sometimes allowed in order to decide upon the efficacy (5); inflammatory markers improve in about 1 week (29). *Duration of remission* after EEN is controversial in the literature. In some studies, the relapse appeared earlier than in those with remission induced by steroids, with 3 (30) – 4.58 months (31); duration of remission was 7 months after EEN *vs.* 10 months after steroids (30). In another study, duration of remission was longer after EEN (32). Ten months after EEN, 39% present a relapse (33). Return to normal food can be made either by beginning with a low-fiber diet or by gradually reintroducing food, over 1-3 weeks, while gradually reducing the formula (4,5).

1.b. PEN is less efficacious in *inducing remission in CD and should not be recommended* (3). In a comparative study in children, EEN induced remission in 42% *vs.* PEN – only in 15%; in children on PEN, half of the requirements were provided by formula (34). Some pediatricians allow the addition of various foods, with a maximum of 10% of the whole energy intake, appearing as not decreasing the efficacy of EN as induction therapy (5).

PEN could be, however, continued after the first 8 weeks of EEN, significantly increasing the rate of *maintaining the remission* (35) and also improving *growth and nutritional status* (especially when associated to other therapies) (5). PEN could be provided in various forms: overnight nasogastric formula in conjunction with normal daytime food (PEN *vs.* normal food, 1 year later: relapse 43 *vs.* 79%,

p<0.02) (36); cyclically – every 1 month out of 4 with EEN (1 year later: reduced activity of CD and of steroids use, with significant height and weight gains) (37); oral supplements of EN in addition to oral eating throughout the day, the preferred option whenever possible (recent study in Israel, using Modulen IBD®, with significant decrease of the activity of CD and of serologic inflammatory markers, as well as improvement of the BMI) (38). Long-term results concerning remission in 44 CD children, using EN over 1-7 years show the following: majority of those continuing PEN did not relapse after remission was established, approximately 50% did not require steroids after the diagnosis and in those who necessitated steroids, their introduction was delayed with a median period of 68 (6-190) weeks; also, the weight Z-scores were improved after 12 months, with no improvement in height Z scores (22).

Recent surveys have evaluated the use of EN in children with CD, across the world. In 2003, EN was used by 62% of pediatric gastroenterologists in Europe *vs.* only 4% in North America (39). In 2011, pediatric gastroenterologists from North America reported that 31% have never used EN, 55% have used it rarely and only 12% do use it regularly. EN has been used significantly more in Canada than in US, including maintaining of remission (40). In the 2nd Pediatric Clinic in Cluj-Napoca, we have used Modulen IBD® in 80% of cases (associated to various therapies), with good results.

PEN has no therapeutic role in UC, however it could be used in those with malnutrition (4, 13).

2. TOTAL PARENTERAL NUTRITION (TPN)

In CD, TPN indications are restricted to: severe malnutrition, complications (fistulas) and nutritional support pre- and postoperatively (4,5). TPN has similar efficacy to EEN, however with much higher costs and more complications (38).

TPN is not effective as a primary therapy for UC, and may even deprive colonocytes of short-chain fatty acids (41). It is restricted only to: severe malnutrition, acute severe colitis, with imminence of toxic megacolon (42) and nutritional support pre- and postoperatively.

3. WHAT TO KNOW ABOUT THE DIET OF THE IBD PATIENT?

Intriguingly, even if no food component has been directly involved in causing IBD, the patients' perception is different. A very recent survey on 244 French adults has shown that 15.6% believed that a diet could initiate the disease and in 47.5% the disease changed the pleasure of eating. Also, 57.8% believed that food can play a role in causing a relapse; moreover, 40% identified food as a risk factor for relapse and 66.8% avoided certain foods, in order to prevent a relapse. One fifth of the patients considered that dietary beliefs and behavior had an impact on their social life. Excluding food was associated with refusing outdoor dining and not sharing the same menu with the family (43).

A systematic review, of existing dietary guidelines written by experts of world / international/ national gastroenterology and nutrition organizations, clearly mentions that *no diet could prevent the relapse* and, therefore, it is not required (41). Diet should be, however, adapted to the individual tolerance to different foods, especially considering other associated medical conditions (41). Foods high in fiber, such as popcorn, nuts, and seeds may result in

cramping, bloating or diarrhea; high fat foods may not be completely absorbed by the digestive tract and could result in gas and diarrhea; milk, cheese, or dairy products may cause abdominal discomfort, bloating, gas and diarrhea in those with lactose intolerance; raw fruits and vegetables may lead to bloating, gas or diarrhea; alcoholic beverages may not worsen IBD, but determine some symptoms (41).

Obviously, when deficiencies are detected, vitamin/mineral supplements should be given: iron (better tolerated and more effective in intravenous administration) (44), vitamin D and calcium – in some opinions also with role in decreasing the relapse (45), vitamin B_{12} (41).

The following rules and food restrictions are recommended during severe relapses, in order not to worsen symptoms: small amounts of food throughout the day; decrease excess saturated fat (fried food, sausages, salami, hot dog, omelet, sauces, margarine, butter, heavy cream), excess sugars and high-fiber foods (cereals, nuts, most raw fruits – except grated apple, banana and melon, most vegetables – beetroot, broccoli, cabbage, cauliflower, spinach, mustard, turnip tops, mushrooms, beans, onion, pepper, pumpkin), avoid dairy products (if lactose intolerant), as well as coffee, alcohol, sweet juice and coke (41).

In conclusion, nutrition is a useful therapy in CD: exclusive enteral nutrition induces remission, partial enteral nutrition decreases the relapse rate, improving growth and nutritional status, total parenteral nutrition has similar efficacy to the enteral one, but with much more adverse effects and higher costs. Nutrition is not effective and should not be used as a primary therapy in UC. As of yet, no diet can prevent the development/relapse of IBD. Some food restrictions are recommended during flares, in order not to worsen symptoms.

ELECTROLYTE DISTURBANCES IN PATIENTS WITH CHRONIC HEART FAILURE – CLINICAL, EVOLUTIVE AND THERAPEUTIC IMPLICATIONS (**Abstract**): Patients with heart failure are, by definition, hemodynamic unstable. Often, this condition may be accentuated by medication (digitalis, diuretics, antiarrhythmics), so that they become more sensitive to electrolyte disturbances, reacting sometimes violently with severe and life threatening rhythm troubles. A**im:** the evaluation of the incidence of electrolyte disturbances in patients diagnosed with chronic heart failure in order to establish a correlation with the evolution, prognosis and therapeutic implications. **Material and methods:** We analyzed retrospectively 100 patients diagnosed with chronic heart failure NYHA II-IV classes, admitted in Cardiology Clinic during 2009 – 2011. We analyzed electrolytic disturbances occurred during different strategies of therapy. **Results:** 100 patients with heart failure were admitted in Cardiology Clinic during 2009-2011, 75 males and 25 females. Diagnosis was established by classical criteria. Evaluation was very complex and included: complete clinical examination, electrocardiogram, echocardiography, chest ray examination and biochemical analyses especially hepatic, renal function and electrolyte status. **Conclusions:** The obtained data showed that electrolyte disturbances are frequent in patients with chronic heart failure, irrespectively of NYHA class. Hyperkalaemia, hypokalaemia and hyponatraemia are associated with diuretic therapy and may play a very important role in subsequent development of life-threatening arrhythmias. **Key words:** ELECTROLYTE DISTURBANCES, HYPOKALAEMIA, HYPERKALAEMIA, HYPONATRAEMIA.

The patient with heart failure is by definition a hemodynamically unstable patient in which any therapeutic gesture initially beneficial, may have unexpected side effects, some of them life-threatening (1). This type of patient usually has electrical instability related to the underlying disease and potentiated under medication (diuretics, digitalis, antiarrhythmics etc.) (1, 2, 3) In these conditions, they become more sensitive to even minor electrolyte balance disturbances, sometimes reacting violently through serious arrhythmias or conduction disturbances. The medication of the patient with heart failure involves complex therapeutic schedule, adapted to the etiopatho-

genic and hemodynamic features of each case. In these schedules the diuretic medication is essential and it is pathophysiologically addressed to the salt and water retention (3). Although well tolerated by most patients, diuretic medication acting at renal level disrupts the electrolyte balance so that, depending on the type of mechanism, on the patients' condition at the time, on the associated medication and diet, there may appear other electrolyte and fluid disorders some of which could be life-threatening (1, 2, 3). Hyponatraemia is the most common electrolyte disorder encountered in intensive care services (its frequency is estimated at 30-40% of the hospitalized patients) (4, 5).

The aim of the study is to evaluate the incidence of electrolyte disorders encountered in patients with heart failure development and to establish a correlation between these disorders and the apparition of certain complications, and the entailed prognosis and therapeutic implications.

MATERIAL AND METHODS

The study is retrospective and included a group of 100 patients, 75 men and 25 women, aged 48-85 years, hospitalized in the 1st Cardiology Clinic between the years 2009-2011 and diagnosed with chronic heart failure of the NYHA II-IV classes.

The classification of patients in the NYHA class of severity of heart failure was as follows (fig. 1):

NYHA Class II - 15 patients: 10 men, 5 women;

NYHA class III - 72 patients: 55 men, 17 women

NYHA Class IV - 13 patients: 8 men, 5 women.

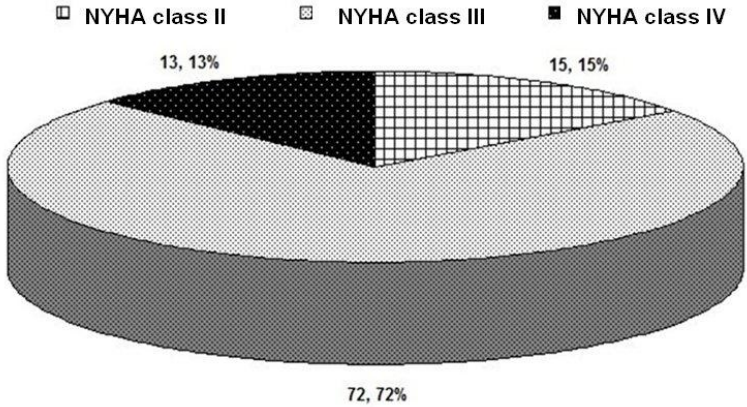

Fig. 1. Distribution of patients according to the NYHA class of heart failure severity.

The diagnosis of heart failure was based on the known and classical clinical and paraclinical data:

- Symptoms and signs of left ventricular failure (shortness of breath of different degrees, cardiac cough, tachycardia with / without gallop rhythm, presence of organic heart breaths and pulmonary rales stasis);

- Signs of right myocardial failure: hepatomegaly, edema in the legs (cardiac type), turgid jugular (level I-III), hepatojugular reflux, with or without ascites.

Paraclinical exploration of the patients included:

- Chest radiography - objectified cardiomegaly (ICT over 0, 55) with or without

signs of pulmonary stasis or pleural effusions.

- Echocardiography (2D, M mode, Doppler) objectified cardiac cavities dilation with decreased contractile function parameters (ejection fraction, shortening fraction), and other aspects: valvular regurgitation, intracardiac thrombus, presence of spontaneous contrast and signs of hypertension pulmonary artery. Echocardiography was essential for identifying the etiology of heart failure.

- Peripheral venous pressure was elevated in most patients with right heart failure component.

- 12 leads surface ECG. There were sought: rhythm or management disturbances, ischemo-lesional changes, overstress of certain cavities, changes due to electrolyte disturbances.

- Biochemical balance included: hepatic function (transaminases, bilirubin, GGT), renal function (urea, creatinine, uric acid, creatinine clearance, RA), serum electrolytes (Na +, K +, Ca + +, Mg + +);

- Paraclinical investigation was complemented with complete blood count, spirogram and determination of blood gases and pH.

Patient evaluation was performed first at the time of admission and subsequently, depending on each particular case, was performed daily during hospitalization.

The etiology of heart failure was as follows (fig. 2):

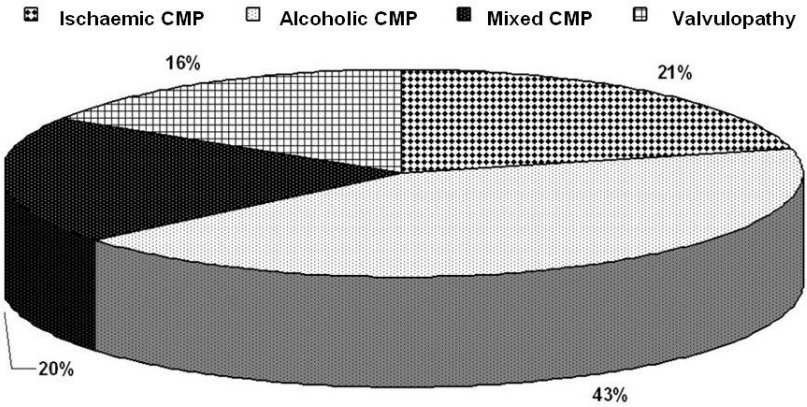

Fig. 2. Etiology of heart failure in the studied group.

- Ischemic dilated cardiomyopathy - in 20% of cases;

- Ethanolic dilated cardiomyopathy - in 45% of cases;

- Mixed dilated cardiomyopathy (ischemic, toxic, diabetic) - 20% of cases.

- Valvular heart disease - 15% of cases.

Etiology was based on history, physical examination and echocardiographic data resulted from examination. In some cases, to these was added the presence of the biochemical markers that supported chronic alcoholism.

Patients' treatment was strictly individualized according to the haemodynamic status at the time of hospitalization, the etiological features, the presence or absence of arrhythmias and/or conduction disturbances and included, besides the

appropriate hygienic-dietary measures, the following (fig. 3):

- Diuretic: loop - 15 patients (15%), spironolactone + loop diuretic combination - 85% of patients;
- Nitrate type vasodilator - 75% of patients;
- Converting enzyme inhibitor (ACEI) - adjusted doses of TA- was administered to 85% of patients (65% received perindopril, 20% received ramipril);
- Beta blocker - 90% of patients (55% carvedilol, bisoprolol 35%);
- Digoxin - 70% of patients;
- Amiodarone - 30% of patients;
- Anticoagulant - 60% of patients;
- Antiplatelet - 75% of patients received aspirin (in 50% of the cases it was associated with anticoagulant), 25% of patients receiving clopidogrel.

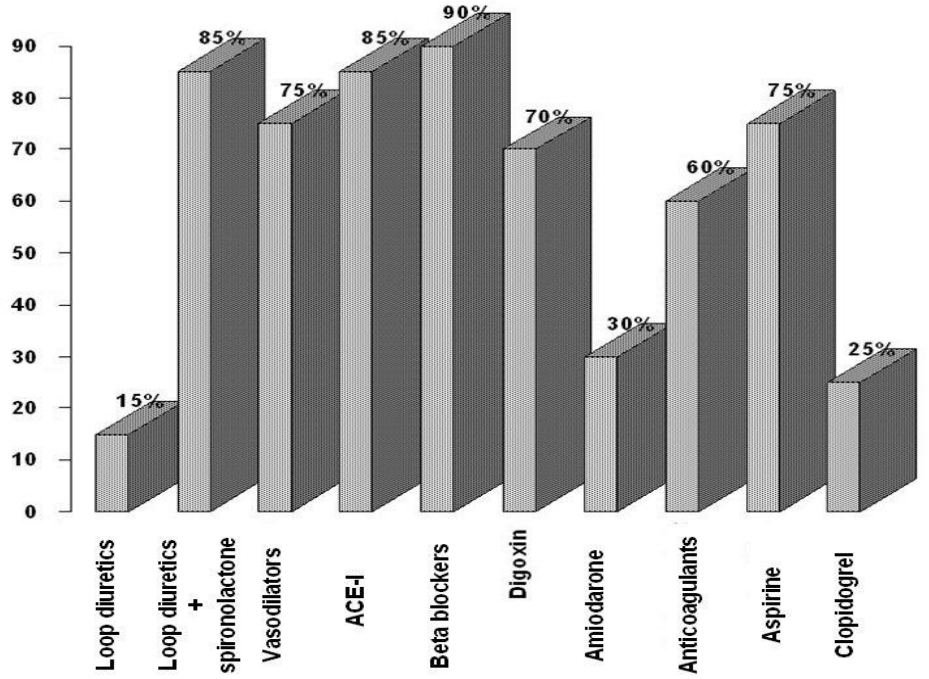

Fig. 3. Treatment of patients in the studied group.

Patients received therapeutic regimens that included combinations tailored to each individual case, as follows:

- Loop diuretic + vasodilator (nitrate) + beta blocker + ACE inhibitor - 10% of cases;
- Loop diuretic + spironolactone + ACE inhibitor + beta blocker + vasodilator (nitrate) - 40% of cases;
- Loop diuretic + spironolactone + ACE inhibitor + beta blocker + digoxin + vasodilator - 20% of cases;
- Loop diuretic + ACE inhibitor + amiodarone + vasodilator - 30% of cases.

All patients received an antiplatelet regimen and in 60% of the cases an anticoagulant administration was necessary.

Introducing the anticoagulant regimen was imposed by the presence of echocardiographic intracavitary thrombus or spontaneous contrast, by the presence of dilated right cavities and other clinical signs suggestive of thromboembolism associated phenomena. Throughout the immobilization in bed there were also injected prophylactic doses of low molecular weight heparin.

The nitrate type vasodilator was used with preference in patients with signs of left ventricular failure considered to be due to ischemia and in patients with evident pulmonary stasis.

RESULTS AND DISCUSSION

The electrolyte disturbances encountered in patients of the group were the following:

Hyperkalaemia (serum K values between 5.8 to 6.5 mmol/l) - present in 65% of patients receiving loop diuretic combination with spironolactone associated with ACE inhibitors. 51% of patients with hyperkalaemia showed electrocardiographic changes suggestive of this type of electrolyte disorder: high T beams, in precordial (5%), ventricular extrasystoles systematized in bi- form and trigeminy ventricular doublets (45% of cases). 35% of these cases were associated with elevated urea and serum creatinine with functional significance of renal failure. The therapeutic conduct consisted of stopping potassium saving diuretic, replacing it only with loop diuretic, infusion of glucose 5% buffered with serum insulin to normalize serum potassium. In patients receiving concomitant digoxin, presence of ventricular extrasystolic arrhythmia imposed the replacement of digitalis with beta blocker.

Hypokalaemia (serum potassium values between 2.1 to 3 mmol/l) was present in 8% of patients that had only loop diuretic therapeutic regimen. 2% had diarrhea as additional contributing factor. Clinically, the patients had asthenia, fatigue, muscle cramps. 5% of the patients receiving concomitant digoxin showed on the electrocardiogram ventricular bigeminy and in 2% of them QT prolongation was found compared with the initial values. The therapeutic conduct consisted of temporarily stopping the diuretic, more potassium (orally or intravenously if necessary) until normalization of serum potassium. The presence of ventricular extrasystoles imposed reconsidering the therapeutic regimen and removing digoxin where present. Lidocaine or beta blocker was used to control arrhythmias.

Hyponatraemia (serum sodium values between 128-110 mmol/l) was present in all patients with NYHA IV class heart failure receiving diuretic therapy. Clinically, these patients presented generalized edema at admission. In 5% of the patients hyponatraemia persisted after stopping diuretic, so it was considered dilution hyponatremia and significantly correlated with increased mortality in this population. Correction of hyponatraemia was difficult, with partial response and limited to fluid restriction and administration of sodium chloride, while continuing the diuretic.

In 15% of cases, these electrolyte disturbances have been associated with inflection of the renal function, that is, increased urea and creatinine values understood as renal functional failure and whose main cause was the diuretic abuse with subsequent reduction in pressure renal perfusion. In 10% of the cases, increased levels of uric acid could be seen (between 9-11 mg%), correlated with the loop diuretic doses. In 7% of cases, renal failure was corrected by

temporary withdrawal of the diuretic and proper hydration. In 8% of cases, it was necessary the administration of vasodilator dose dopamine (2-3 mcg/kg/min).

CONCLUSIONS

Electrolyte disturbances are common in patients with heart failure development, regardless of NYHA functional class. In most cases this is due to medication, especially to the diuretic therapy. From this perspective, certain drug combinations as loop diuretics with digoxin, potassium saver diuretics with ACE inhibitors present a more important risk. Correcting these imbalances is a major emergency as they often are life-threatening, representing the substrate for different arrhythmias including the ventricular which can represent a vital threat.

Hyponatraemia is an independent negative prognostic factor especially in patients enrolled in the NYHA IV functional class and it is often associated with increased mortality.

Knowing these electrolyte disturbances that can occur at any time in the evolution of patients with heart failure imposes attention to the choice of therapeutic regimen, caution in dosing and combination of drugs, which are, in fact, absolutely necessary.

URIC ACID, CARDIOVASCULAR EVENTS AND RENAL DYSFUNCTION: A CIRCUMSTANTIAL CONNECTION? (Abstract): **Aim**: The relationship between asymptomatic hyperuricemia, cardiovascular events and renal dysfunction was studied (affirmed or challenged) long time ago. To investigate this relationship we conducted this study. **Material and methods**: We analyzed 163 patients consecutively admitted in the Intensive Cardiac Care Unit of the 1st Cardiology Clinic, County Hospital "St. Spiridon" Iasi. The cut-off value of serum uric acid was defined as 7 mg%. There were recorded anthropometric, anamnesis, clinical and paraclinical data. **Results:** We compared the normal uricemia group (108 patients) with the hyperuricemia group (55 patients). The serum uric acid value was 5.22+/-1.16 mg% in the normouricemia group and 8.58+/-1.86 mg% in the hyperuricemia group. The statistically significant differences between the two groups relate to sex, smoking as cardiovascular risk factor, diastolic blood pressure and ejection fraction (lower in the hyperuricemia group were the dilated cardiomyopathy prevail). If the patients are grouped according to creatinine *clearance* less than or greater than 60 ml / min we found statistically significant differences between the two groups in terms of serum uric acid value ($p < 0.001$), age ($p < 0.001$), renal dysfunction and dyslipidaemia (p 0.001). **Conclusions:** The analysis performed doesn't demonstrate the role of uric acid as independent risk factor in a group that includes patients with different heart diseases (dilated cardiomyopathy, ischemic heart disease or hypertension). **Key words:** URIC ACID, CARDIOVASCULAR, RENAL DYSFUNCTION

Relația dintre hiperuricemia asimptomatică, evenimentele cardiovasculare şi disfuncția renală a fost analizată, afirmată (1) sau contestată (2) de mult timp, începând cu semnalul princeps lansat în 1879 de către Mohamed (3). Datele recente indică asocierea pierderii evolutive a uricazei la om (proces inițiat, se pare, în urmă cu aproximativ 24 milioane de ani) (4) cu o serie de avantaje evolutive: o capacitate antioxidantă înaltă şi longevitate sporită, menținerea valorilor tensiunii arteriale în cazul unei diete hiposodate (5), sporirea inteligenței şi neuroprotecție. Pe de altă parte, sunt dovezi în favoarea rolului potențial de toxină cardiorenală a acidului uric (6), hiperuricemia fiind asociată cu numeroase comorbidități: obezitate, sindrom

metabolic, diabet zaharat, hiperlipoproteinemie, hipertensiune arterială, insuficienţă cardiacă sau boală cronică de rinichi (7, 8, 9). Caracterul de factor de risc independent al acidului uric este însă un subiect de controversă, unii autori susţinând idea că până nu apar noi date, pacienţii hiperuricemici ar trebui să fie evaluaţi în direcţia prezenţei altor factori de risc deja validaţi (10). Intenţia de a investiga relaţia dintre nivelele acidului uric, evenimentele cardiovasculare şi disfuncţia renală a stat la baza realizării acestei lucrări.

MATERIAL ŞI METODE

Au fost incluşi în studiu 163 de pacienţi internaţi consecutiv în Unitatea de Supraveghere şi Tratament Avansat al pacienţilor Cardiaci Critici (USTACC) din cadrul Clinicii I Medicale Cardiologice "C. I. Negoiţă", Spitalul Clinic Judeţean de Urgenţă "Sf. Spiridon" Iaşi, în perioada iunie – decembrie 2011, 106 (65,03%) bărbaţi şi 57 (34,97%) femei cu vârsta medie 64,92 +/- 11,32 (limite 36-89). Au fost consemnate datele antropometrice (talie, greutate, indicele de masă corporală), anamnestice (antecedente personale coronariene, cerebrale şi periferice; factorii de risc cardiovascular: fumat, dislipidemie, hipertensiunea arterială, diabetul zaharat), clinice (valorile tensiunii arteriale, frecvenţei cardiace, diagnosticul principal) şi biochimice referitoare la funcţia renală (acidul uric seric, urea serică, creatinina serică, *clearance*-ul de creatinină calculat conform formulei Cockcroft-Gault), dislipidemie (colesterolul seric, trigliceridele serice, HDL-C, LDL-C) şi generale (hemoleucograma şi glicemia). S-a efectuat o electrocardiogramă (s-a consemnat ritmul şi descrierea traseului) şi un examen ecocardiografic transtoracic utilizând un ecocardiograf Esaote MyLab™ 30 GOLD Cardiovascular cu un transductor *phased-array* de 2-5 MHz (cu măsurarea diametrelor şi dimensiunii pereţilor cordului, aprecierea funcţiei sistolice şi diastolice ventriculare, diametrul venei cave inferioare) în cazul fiecărui pacient. Analiza statistică s-a realizat utilizând *Microsoft ® Office Excel 2003* şi *SPSS 14,0 for Windows*. Analiza corelaţiilor s-a efectuat cu ajutorul coeficientului de corelaţie Pearson. Semnificaţia statistică a fost luată în consideraţie pentru un nivel $p < 0,05$.

REZULTATE

Analiza lotului s-a efectuat în funcţie de nivelul acidului uric seric. Deoarece în literatură valoarea discriminativă pentru normo- şi hiperuricemie este variabilă (5,12 mg% în studiul Framingham, 1987 şi diferenţiată peste 6 mg% la femei şi peste 8 mg% la bărbaţi în studiul lui Filippatos et al) (9) în acest studiu s-a considerat valoarea cut-off peste 7 mg%. În funcţie de această variabilă lotul a fost analizat comparativ: normouricemici (n = 108) *vs.* hiperuricemici (n = 55) (tab. I).

Singurele diferenţe statistic semnificative între cele două grupuri se referă la sex, la prezenţa tabagismului cronic ca şi factor de risc cardiovascular şi la valorile tensiunii arteriale diastolice. S-au evaluat valorile medii ale acidului uric în cele două grupuri, cu evidenţierea diferenţelor semnificative care ţin de disfuncţia renală (tab. II şi III).

Toate celelalte variabile biologice sunt similare în cadrul grupului cu sau fără hiperuricemie. Există o diferenţă statistic semnificativă între fracţia de ejecţie, mai redusă în grupul cu hiperuricemie în care au predominat însă şi cazurile prezentând cardiomiopatie dilatativă (fig. 1).

TABELUL III

Variabile ecocardiografice ale pacienților din lotul studiat

n (%) sau medie +/-DS (mediana)	Normouricemie (n = 108)	Hiperuricemie (n = 55)	Valoarea p
Prezența HVS.	57 (52,78)	31 (56,37)	0,726
Fractia de ejectie (%)	61,2+/-3,1	55,9+/-4,1	0,036

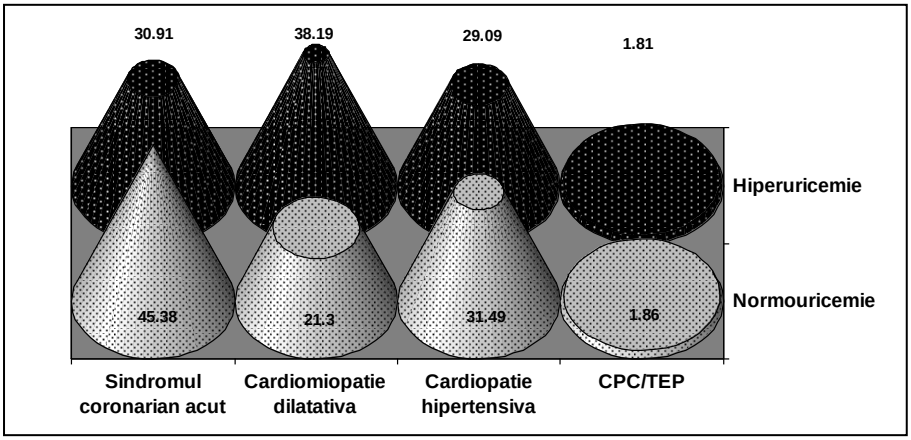

Fig. 1, Distribuția afecțiunilor cardiace (%) în cadrul celor două grupuri cu normo- şi hiperuricemie.

Nu s-au evidențiat diferențe semnificative statistic în ceea ce priveşte diagnosticul principal al afecțiunii cardiace care a determinat internarea pacienților. În cazul grupul pacienților cu hiperuricemie dar cu o valoare la limită s-au administrat mai frecvent sartanii (tab. IV).

Grupând pacienții lotului studiat în funcție de valoarea *clearance*-ului de creatinină mai mic sau mai mare decât 60 ml/minut am constatat existența unor diferențe semnificative statistic între cele două grupuri atât în ceea ce priveşte valoarea acidului uric seric ($p < 0,001$), vârsta ($p < 0,001$), disfuncția renală (valorile ureei şi creatininei serice, cum era de aşteptat) şi prezența HLP (p 0,001), a valorilor colesterolului seric (p 0,003) dar şi a trigliceridelor serice (p 0,010).

TABELUL IV

Medicația cardiovasculară administrată pacienților din lotul studiat

n (%)	Normouricemie (n = 108)	Hiperuricemie (n = 55)	Valoarea p
Betablocante	44 (40,74)	26 (47,28)	0,596
IECA	51 (47,23)	26 (47,28)	0,136
Sartani	10 (9,26)	1 (1,81)	0,048
Anticalcice	39 (36,12)	19 (34,55)	0,855
Diuretice	77 (71,30)	39 (70,91)	0,123

Legendă: IECA inhibitori ai enzimei de conversie a angiotensinei.

Pentru o grupare în funcţie de un alt nivel de *cut-off* al *clearance*-ului de creatinină (30 ml/min) diferenţele între valorile acidului uric nu mai sunt semnificative, menţinându-se diferenţa în ceea ce priveşte prezenţa disfuncţiei renale (uree serică p 0,001, creatinina serică p < 0,001), precum şi a antecedentelor cerebro-vasculare (p 0,043) şi a tratamentul cu IECA (p < 0,001).

DISCUŢII

Acidul uric, rezultat al catabolismului purinelor prin intervenţia xantinoxidazei, este un acid slab (pKa 5,8) care se găseşte în compartimentul extracelular sub formă de urat de sodiu, fiind supus unor multiple mecanisme reabsortive şi secretorii la nivelul tubilor contorţi renali şi doar un procent de 8-12% din acidul prezent iniţial în ultrafiltrat este excretat (8). Acest model operaţional generează o serie de întrebări: când şi de ce am pierdut în cursul evoluţiei uricaza (urat oxidaza), enzimă care cu excepţia umanoizilor şi primatelor mari este responsabilă de metabolizarea acidului uric în alantoină, un produs mult mai solubil şi în consecinţă de ce păstrăm concentraţia serică a acidului uric la valori de 3,7-7 mg% la om faţă de 0,5-1,5 mg% la celelalte animale, reprezintă această modificare un avantaj evolutiv sau hiperuricemia s-a transformat treptat într-un dezavantaj fiind implicată în calitate de factor de risc încă neprobat a fi independent (10) în geneza unor afecţiuni cardio-vasculare şi renale severe. Analiza este şi mai rafinată dacă se iau în consideraţie intervale distincte ale nivelelor serice ale acidului uric, unele în zona considerată a fi normală (3,03-5,04 mg% *vs.* 5,05-5,88 mg% *vs.* 5,89-9,58 mg) (11). Relaţia potenţială dintre acidul uric şi patologia cardiovasculară ar putea genera atitudini terapeutice specifice: administrarea de uricozurice (probenecid, benzbromarona, sulfinpirazona şi chiar losartanul şi fenofibratul), de inhibitori ai xantinoxidazei (febuxostat, oxipurinol) sau chiar a unei uricaze sintetice (rasburicasa) (12, 13).

În studiul efectuat, hiperuricemia nu s-a dovedit asociată cu prezenţa sindromului coronarian acut ci doar cu prezenţa disfuncţiei renale moderate (conform clasificării KDOQI - *Kidney Disease Outcomes Quality Initiative*), relaţie care nu a fost evidenţiată în cazul afectării renale severe. Studii recente (9) au arătat similar că această asociere este semnificativă doar când hiperuricemia este un marker al creşterii activităţii xantin-oxidazei şi nu când aceasta este determinată de către alterarea eliminării renale a acidului uric. Acest studiu nu evidenţiază corelaţii între nivelurile acidului uric şi tipul afecţiunii cardiace a pacienţilor incluşi în lot.

Limitele studiului sunt reprezentate de către mărimea redusă a lotului, natura observaţională a analizei fără urmărirea în evoluţie a ratei de apariţie a evenimentelor cardiovasculare sau de progresie a disfuncţiei renale.

CONCLUZII

Analiza efectuată nu a demonstrat diferenţe semnificative între cele două grupuri cu normo sau hiperuricemie. Valoarea uricemiei constatată în cazul evaluării unei disfuncţii renale medii, nu se menţine în cazul asocierii unei disfuncţii renale severe.

NOUTĂȚI

REFACEREA VEDERII DUPĂ TRANSPLANTUL DE CELULE CU ROL DE FOTORECEPTORI

Transplantul celular ar putea reprezenta o soluție terapeutică în cazul orbirii provocate de pierderea fotoreceptorilor. Deși precursorii transplantați ai celulelor cu bastonașe pot migra la nivelul retinei adulte, unde se diferențiază pentru a dobândi caracteristicile morfologice speciale ale celulelor fotoreceptoare mature, întrebarea fundamentală care persistă este cea legată de posibilitatea ca un transplant de celule cu potențial de fotoreceptori să poată îmbunătăți performanța vizuală. Există o serie de dovezi recente care relevă o ameliorare a vederii funcționale mediate de celule cu bastonașe la șoarecii $Gnat1^{-/-}$, la care funcția celulelor cu bastonașe s-a pierdut, ei reprezentând un model de orbire congenitală staționară nocturnă. S-a putut astfel evidenția faptul că precursorii transplantați al acestor celule formează triada clasică a conexiunilor sinaptice cu neuronii bipolari la nivel retinian. Celulele fotoreceptoare nou integrate sunt responsabile de percepția luminoasă, cu o cinetică similară celulelor fotoreceptoare adulte.Se demonstrează astfel fezabilitatea acestui tip de transplant ca o strategie terapeutică pentru refacerea vederii după degradări retiniene.(Pearson R.A., Barber A.C. Rizzi M. et al. Restoration of vision after transplantation of photoreceptors. *Nature* 2012; 99-103)

FEATURES OF BRAIN STEM TUMORS IN CHILDREN. (Abstract). Brain stem tumors account for about 10-20% of childhood brain tumors. Peak incidence for these tumors occurs around age 6 to 7 years. **Aim:** Despite their severity and poor prognosis, brain stem tumors remain an area of intense research with regard to their diagnosis and management. **Material and methods:** In the interval 2003-2010, 8 children (4 girls and 4 boys) aged 2-13 years (mean age 6.82), diagnosed with brain stem tumors were followed up. Disease history, onset symptoms, complete physical, laboratory and imaging investigations, and individualized therapeutic approach have been reviewed. Family history was considered to be of particular clinical importance. Monitoring the disease progression was possible until the time of death (when it occurred in hospital) or by information provided by the family and family physician in cases where death occurred at patient's home. **Results**: Clinical signs and symptoms depend on tumor location, its aggressiveness, and patient's age. Progressive neurological deficits, signs and symptoms caused by increased intracranial pressure, visual disturbances, behavioral disorders, seizures, endocrine disruption, failure to thrive may occur in various combinations. In only 50% of our cases the tumor could be removed. Imaging proved highly suggestive for a brain stem tumor. Histopathological examination diagnosed one pilocytic astrocytoma (grade I), one fibrillary astrocytoma (grade II), one anaplastic astrocytoma (grade III), and one glioblastoma multiforme (grade IV). In the remaining 4 cases imaging was suggestive for glial tumors. Multimodal therapy was used in 2 patients, 7 received adjuvant chemotherapy, and in 1 case no therapy was administered because the tumor rapidly progressed to death. Seven of our patients died on an average of 6.28 months after the diagnosis (range 2 to 9 months). A family history of brain tumors in 2 of our cases supports the hypothesis of genetic factors involvement. **Conclusions**: Brain stem tumors are still difficult to investigate, and the results on their long- and medium-term survival remain uncertain.
Key words: TUMOR, BRAINSTEM, SURVIVAL, CHILD

Tumorile sistemului nervos central reprezintă a doua malignitate a copilăriei, fiind cea mai frecventă tumoră solidă din pediatrie(1, 2). Clasificarea histo-patologică este complexă şi se bazează în principal pe tipul histologic al celulei de origine, coroborată cu dezvoltarea embriologică (3). Semnele şi simptomele clinice depind de localizarea tumorală, de agresivitatea sa şi de vârsta pacientului. Deficitele neurologice progresive, semnele şi simptomele determinate de creşterea presiunii

intracraniene, tulburările de vedere, tulburările comportamentale, convulsiile, tulburările endocrine, stagnarea creşterii şi întârzierea achiziţiilor psiho-motorii sau chiar involuţia acestora pot apare izolat sau în diverse asocieri (2). Durata evoluţiei poate varia de la câteve zile până chiar la câţiva ani, în funcţie de agresivitatea celulei tumorale şi de ritmul creşterii neoplasmului. Este deja bine statuată legătura între tumorile cerebrale şi anumite sindroame genetice: neurofibromatoza tip I, sindromul Li-Fraumeni, scleroza tuberoasă, sindroamele Von Hippel-Lindau, Turcot şi Gorlin (4). Evaluarea imagistică include computer-tomografia (CT) şi rezonanţa magnetică nucleară (RMN) care se completează reciproc şi descriu localizarea tumorală, extensia locală, compresiunea pe structurile de vecinătate, hidrocefalia supraiacentă. Tomografia cu emisie de pozitroni poate diferenţia recidiva tumorală de necroza, cicatricile postoperatorii sau edemul local postterapeutic (1). Intervenţia chirurgicală are drept scop îndepărtarea unei cât mai mari porţiuni tumorale, obţinerea probei necesare examinării histopatologice şi rezolvarea hidrocefaliei. Intervenţia chirurgicală este urmată de chimio-radioterapie în funcţie de tipul histopatologic tumoral. Datorită toxicităţii neurocognitive a radioterapiei, în prezent sunt preferate radioterapia hiperfracţionată, radiochirurgia stereotaxică sau terapia cu protoni, mult mai puţin agresive pe ţesutul nervos nobil decât radioterapia standard conformaţională (5, 6, 7). Supravieţuirea cazurilor cu grad redus de malignitate (I şi II) este de aproximativ 80% după o rezecţie tumorală de bună calitate. Spre deosebire de acestea, tumorile cu grad mare de malignitate au un prognostic mult mai rezervat, cu o supravieţuire la 5 ani de sub 20% (1, 2). Tumorile trunchiului cerebral reprezintă 10-20% din totalul tumorilor cerebrale din pediatrie şi au per se un prognostic extrem de rezervat datorită structurilor nobile şi a centrilor vitali de la acest nivel. Incidenţa maximă se situează la vârsta de 6-7 ani. Simptomatologia diferă în funcţie de tipul dezvoltării tumorii (infiltrativ sau nodular) şi se poate manifesta sub forma deficitelor neurologice diverse, a hipertensiunii intracraniene, a ataxiei, hemiparezelor, nistagmusului, a tulburărilor senzoriale în diverse asocieri. Diagnosticul histo-patologic este de cele mai multe ori doar suspectat prin descrierea imagistică (leziuni focale sau infiltrative, cu structură mixtă) deoarece intervenţia chirurgicală implică riscuri majore. Marea majoritate a acestor tumori sunt glioame cu grad diferit de anaplazie dar se pot întâlni şi tumori neuroectodermale primitive (PNET) mai ales în cazul tumorilor focale (2). Planul terapeutic este individualizat pentru fiecare pacient în parte, urmând caracteristicile clinice, imagistice şi histologia suspectată sau chiar certă (în cazurile care au permis biopsia tumorală); terapia poate asocia radioterapie (posibilă în funcţie de vârsta pacientului şi de preferat cu modalităţi radioterapice care să minimalizeze efectele adverse pe ţesuturile nervoase nobile de vecinătate) şi chimioterapie antitumorală adjuvantă (rezervată cazurilor cu diagnostic histopatologic de astrocitom cu grad mare de malignitate sau PNET). Supravieţuirea medie variază între 4 şi 15 luni şi doar 6-10% supravieţuiesc la 2 ani de la diagnostic (1, 2). O rată de supravieţuire mai mare (de 94% la 4 ani de la diagnostic) s-a observat în cazurile de tumori focale care au beneficiat de o exereză chirurgicală de bună calitate urmată de radioterapie (2).

MATERIAL ŞI METODĂ

În perioada 2003-2010 în cadrul Clinicii a IV-a Pediatrie, Secţia de Hemato-Oncologie Pediatrică a Spitalului Clinic de Urgenţă pentru Copii „Sf. Maria" Iaşi au fost urmăriţi un număr de 8 pacienţi diagnosticaţi şi trataţi pentru tumori ale trunchiului cerebral. Studiul prezent a analizat dosarele medicale ale acestor pacienţi din punct de vedere al istoricului bolii, al simptomatologiei de debut şi al examenului clinic complet precum şi al investigaţiilor paraclinice, imagistice şi al conduitei terapeutice individualizate de la caz la caz. S-au notat şi antecedentele heredo-colaterale considerate a avea o importanţă clinică deosebită. Monitorizarea evoluţiei a fost posibilă pînă la momentul decesului (când acesta s-a produs în spital) sau prin informaţiile furnizate de către familie şi de către medicul de familie în cazurile când decesul s-a produs la domiciliul pacientului.

REZULTATE ŞI DISCUŢII

Într-o perioadă de timp de 8 ani în cadrul Clinicii a IV-a Pediatrie, Secţia de Hemato-Oncologie Pediatrică a Spitalului Clinic de Urgenţă pentru Copii „Sf. Maria" Iaşi au fost urmăriţi 8 pacienţi diagnosticaţi cu tumori de trunchi cerebral, 4 fete şi 4 băieţi deci o repartiţie egală pe sexe. În medie a fost diagnosticat un caz nou pe an. Vârsta de debut a variat de la 2 la 13 ani, cu o medie de 6,82 ani, ceea ce se încadrează în media de vârstă citată de literatura internaţională.

Debutul afecţiunii a fost reprezentat de manifestări de hipertensiune intracraniană, pareze ale nervilor cranieni, nistagmus, hemipareze şi tulburări de deglutiţie instalate brutal sau insidios şi care au determinat adresarea către serviciile de sănătate la intervale de timp variabile în funcţie de brutalitatea instalării simptomatologiei. Durata debutului a variat de la câteva zile la 5 luni.

Examinarea clinică a relevat prezenţa deficitelor neurologice diverse, a parezelor de nervi cranieni, a nistagmusului şi a fost urmată de investigaţia imagistică prin computer-tomograf (CT) şi rezonanţă magnetică nucleară (RMN) care au descris formaţiunile expansive cu structură mixtă şi aspect neomogen la nivelul trunchiului cerebral; în 7 cazuri diagnosticul imagistic a fost de tumoră infiltrativă la nivelul punţii cu extensie în pedunculii cerebrali şi la nivelul ventriculului IV şi doar într-un singur caz a fost descrisă o tumoră cu aspect nodular la nivel bulbo-pontin.

În doar 50% dintre cazurile studiate a fost posibilă intervenţia chirurgicală de exereză tumorală: 1 caz cu ablaţie tumorală parţială, 2 cazuri cu ablaţie tumorală subtotală şi 1 caz care a beneficiat doar de biopsie tumorală. Dealtfel biopsia tumorală nu este obligatorie în cazurile în care descrierea imagistică este înalt sugestivă pentru o tumoră de trunchi cerebral. Examinarea histopatologică a diagnosticat în aceste cazuri 1 astrocitom pilocitic (grad I de malignitate), 1 astrocitom fibrilar (grad II), un astrocitom de grad III anaplazic şi 1 caz de glioblastom multiform cu grad maxim de anaplazie. În celelalte 4 cazuri descrierea imagistică a fost sugestivă pentru tumori gliale.

Terapia multimodală a inclus radioterapia la 2 pacienţi, doza aplicată fiind de 34 Gy divizată în 17 fracţiuni. Aceste 2 cazuri sunt reprezentate de glioblastomul multiform şi de un caz fără biopsie tumorală. 7 din 8 cazuri au fost incluse în protocolul de chimioterapie adjuvantă (după obţinerea consimţământului informat al familiei) şi au primit Temozolomidă în doză de 150 mg/m^2/zi, timp de 5 zile consecutiv, repetat la 28 de zile interval. Cel de-al 8-lea caz nu

a primit chimioterapie datorită evoluţiei rapide a simptomatologiei care a impus transferul în Clinica de Neurochirurgie unde a şi decedat. Asociat chimioterapiei pacienţii au primit şi terapie antiedematoasă cerebrală şi simptomatice.

Evoluţia sub tratamentul menţionat a inclus scurte perioade de ameliorare urmate de recrudescenţa şi agravarea simptomatologiei neurologice, cu decesul a 7 dintre pacienţi în medie la 6,28 de luni de la momentul diagnosticului. Durata supravieţuirii la aceşti pacienţi a variat de la 2 luni la 9 luni. Un pacient este în viaţă la 18 luni de la diagnostic.

O menţiune specială este reprezentată de prezenţa în antecedentele heredo-colaterale a doi dintre pacienţi a rudelor de gradul I şi respectiv III cu tumori cerebrale: pacienta R. G. de 13 ani cu astrocitom anaplazic are un frate diagnosticat cu astrocitom pilocitic recidivant de Ventricul IV (şi care se află în prezent în chimioterapie cu Temozolomidă) iar pacienta D. I. de 5 ani decedată prin tumoră pontomezencefalică nebiopsiată a avut bunica maternă decedată tot prin tumoră cerebrală. Aceste cazuri susţin ipoteza implicării unor factori genetici în etiopatogenia tumorilor cerebrale, chiar dacă acest lucru nu a putut fi dovedit la aceste paciente.

În evoluţie 2 cazuri au prezentat manifestări rar citate în literatură: o pacientă a dezvoltat tulburări de personalitate şi comportamentale, cu elemente de heteroagresivitate iar un al doilea pacient a dezvoltat în perioada postoperatorie tulburări majore de deglutiţie, cu pneumonie de aspiraţie, ceea ce a impus traheostomia de necesitate.

În cele ce urmează prezentăm cazul pacientului de sex masculin, M. L. C., în vârstă de 2 ani şi 9 luni, care s-a internat în luna martie 2010 în Secţia Hemato-Oncologie a Spitalului de Urgenţă pentru Copii „Sf. Maria" Iaşi pentru investigarea unui deficit neurologic progresiv, instalat cu o lună anterior internării. La internare prezenta stare generală relativ bună, afebril, asimetrie facială cu ptoză palpebrală dreaptă, asimetria comisurilor bucale, tulburări de echilibru, reflexe osteo-tendinoase vii, tetrapareză spastică, retard psihomotor. Investigaţiile biologice (hemoleucogramă, sindrom inflamator, probe hepatice şi renale) au fost în limite normale. Traseul electroencefalografic nu a decelat modificări. Evaluarea CT a descris prezenţa unei leziuni heterogene la nivel bulbar şi parţial pontin, imprecis delimitată, cu minimă priză de contrast periferică şi dimensiuni de 1,9⁄2,7⁄2,8 cm, asociată cu o zonă de 4⁄6 mm pontină cu densitate sugestivă de hemoragie recentă; leziunea determină efect de masă asupra parenchimului bulbo-pontin adiacent şi asupra arterei vertebrale stângi pe care o deplasează lateral. S-a completat evaluarea imagistică prin efectuarea RMN care a descris o leziune mixtă, multiloculată situată pontin inferior până la nivelul medullei oblongata, cu dimensiuni de 2,6⁄2,7⁄3,2 cm şi care amprentează ventriculul IV fără a determina însă hidrocefalie supraiacentă (Fig. 1 şi 2).

Descrierea imagistică era sugestivă pentru o tumoră de tip astrocitar cu localizare bulbo-pontină, motiv pentru care s-a iniţiat terapie antiedematoasă cerebrală şi chimioterapie cu Temozolomidă, 200 mg⁄m2⁄zi, 5 zile, repetat la 28 de zile interval. A primit 4 cure de chimioterapie, fără a dezvolta toxicitate hematologică majoră dar cu instalarea unui sindrom Cushing iatrogen corticoterapiei. În luna iulie 2010 s-a intervenit neurochirurgical cu ablaţia tumorală subtotală (debulking intracapsular cu urmărirea planului de clivaj de la nivelul polului inferior

până în vecinătatea protuberanței unde tumora infiltrează parenchimul). Examinarea histo-patologică a descris un astrocitom pilocitic (grad I de malignitate) cu histochimie: GFAP pozitiv difuz, VIM pozitiv difuz, NFT negativ, SYN negativ, Neu N negativ, Ki 67 pozitiv în 1-2% din celulele tumorale. Evoluția postoperatorie imediată a fost favorabilă, cu ameliorarea tetraparezei dar cu menținerea disfagiei; în evoluție disfagia s-a accentuat şi a fost urmată de complicații, cu pneumonie de aspirație care a impus traheostomia (menținută 10 zile), antibioticoterapia intravenoasă cu spectru larg, terapia simptomatică şi kinetoterapia. După remiterea simptomelor respiratorii ameliorarea clinică a permis suspendarea traheostomei. Pacientul a continuat kinetoterapia recuperatorie cu ameliorarea evidentă neurologică şi a rămas în supraveghere oncologică (dat fiind gradul I mic de malignitate al celulei tumorale). Menține tulburările de deglutiție minore şi sindromul Cushing iatrogen. Monitorizarea imagistică repetată a evidențiat un minim rest tumoral (nodul ovalar gadolinofil de 9⁄9⁄7 mm anterolateral dreapta la nivelul punții precum şi un chist bulbocervical bilobat de 8⁄8⁄14 mm), fără modificări ale sistemului ventricular. Consultul neurochirurgical a opiniat pentru temporizarea reintervenției şi urmărirea iterativă clinico-imagistică.

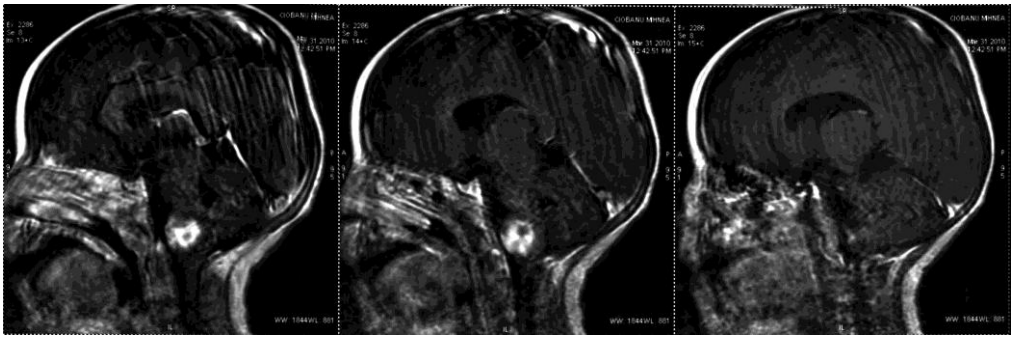

Fig. 1. RMN preoperator postcontrast intravenos cu secțiuni sagitale care descriu leziunea preponderent pontină cu structură mixtă.

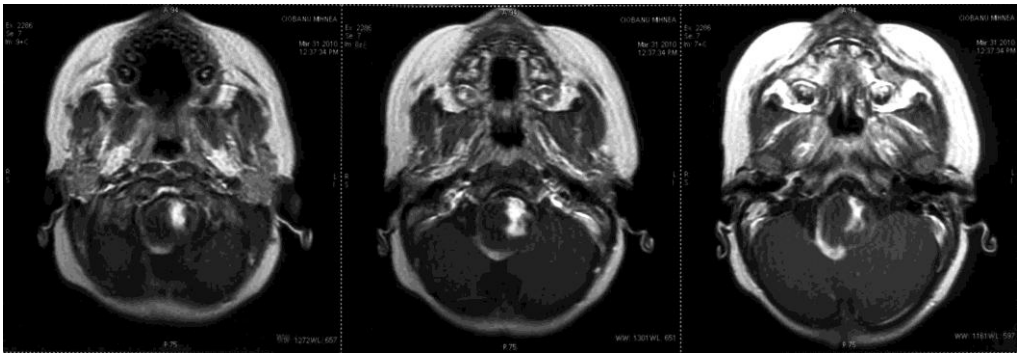

Fig. 2. RMN preoperator postcontrast intravenos cu secțiuni transversale care descriu leziunea preponderent pontină cu structură mixtă.

CONCLUZII

Datele prezentate susțin incidența scăzută a tumorilor de trunchi cerebral în pediatrie, în cazul acestui studiu fiind diagnosticat un caz nou pentru fiecare an de monitorizare. Manifestările de debut şi examenul clinic au orientat diagnosticul spre o patologie tumorală de trunchi cerebral care a fost confirmată prin evaluarea imagistică (CT şi RMN). Doar jumătate dintre pacienți au beneficiat de diagnostic histopatologic prin biopsie tumorală. Conduita terapeutică a asociat radio-şi chimioterapie conform protocoalelor internaționale în vigoare dar evoluția a fost progresivă şi a dus la decesul a 87,5% dintre pacienți în mai puțin de 12 luni de la diagnostic. Singurul caz al unui pacient supraviețuitor la 18 luni de la diagnostic este al unui băiat în vârstă de 2 ani la momentul diagnosticării; a fost confirmat cu astrocitom pilocitic nodular pontin prin rezecție tumorală subtotală şi menține un minim rest tumoral pentru care necesită evaluare în dinamică. Tumorile trunchiului cerebral rămân un capitol al patologiei tumorale pediatrice dificil de explorat şi cu rezultate incerte în ceea ce priveşte supraviețiurea pe termen mediu şi lung.

DEPRESSION AND ZUNG SELF-RATING DEPRESSION SCALE IN PARKINSON'S DISEASE (Abstract): Patients affected by Parkinson's disease (PD) experience many non-motor symptoms, including depression. Depression has a negative impact on everyday activities and quality of life. Still, depression is underrecognized and undertreated overall. Among the instruments used to investigate depression in PD, Zung Self-Rating Depression Scale (ZSRDS) is a widely-used questionnaire for screening depressive symptoms and for measuring progress following treatment. In this article, we review the literature concerning depression associated with PD, paying specific attention to ZSRDS as a tool that investigates depression to guide treatment decisions. **Keywords:** DEPRESSION, ZUNG SELF-RATING DEPRESSION SCALE, PARKINSON'S DISEASE.

Parkinson disease (PD) was first described in 1817 by the British doctor James Parkinson (1) and is currently ranked as second to Alzheimer's disease as the most prevalent age-related complex, idiopathic neurological disorder. It emerges from deterioration of the dopaminergic neurons from *substantia nigra* and is characterized by bradykinesia, tremor (especially in the hands and/or arms) and muscle rigidity along with impaired gait, and posture (2-5).

Although PD is known especially for the debilitating motor symptoms, it also determines multiple non-motor deteriorations (6). Non-motor symptoms may appear before motor symptoms and include depression, anxiety, sleep disturbances, cognitive dysfunction, dementia, olfactory deficits and constipation (2-6).

Depression and Parkinson's disease

Depression is a common psychiatric disorder and global public health problem. It is the third leading cause of years lived with disability worldwide and is associated with a high risk of early mortality from suicide (7,

8). As with Parkinson's disease, its prevalence is influenced by both genetic factors and environmental exposures (9, 10).

Due to the influence on neurotransmissions, depressive disturbances may occur in up to 50% of patients diagnosed with PD which negatively impact the quality of life, mobility, cognition, functionality and other comorbidities (11). Depressed PD patients experience faster cognitive and motor decline, lower quality of life and enhanced mortality compared to non-depressed PD patients (12).

Depression can manifest several years before the onset of motor symptoms, but it can appear at any phase during PD. General risk factors for depression in PD include longer duration of the disease, motor disability, akinetic-rigid variant of PD, other neuropsychiatric symptoms, sleep disorders, restless legs syndrome, higher daily doses of levodopa, female gender and younger age (13).

In patients diagnosed with PD, depression is underrecognized, neurologists failing to identify its presence in more than 50% of the cases, while the calculated diagnostic accuracy is 35% (14). Similar symptoms like reduced facial expression, fatigue, problems with sleeping, diminished appetite and psychomotor retardation contribute to the underdiagnosis of depression in patients with PD (15).

In a recent review article, Santiago et al concluded that "the precise mechanism underlying the association between depression and PD remains unknown" although some hypothesis (e.g. serotonin hypothesis, inflammation hypothesis) are investigated. Throughout the world PD affects 7-10 million people and considering that it is an incurable progressive neurodegenerative disorder and the absence of completely validated biomarkers for establishing the early stages of the disorder, therapeutic intervention is challenging (16).

Goodarzi *et al.* showed in a systematic review that tricyclic antidepressants (TCAs), specifically amitriptyline, proved to be beneficial for mood, yet this was counterbalanced by the adverse effects. Also, it was mentioned that selective serotonin reuptake inhibitors (SSRIs) exhibited some benefit, but the SSRIs could worsen PD symptoms of restless legs, periodic limb movement and REM sleep behavior disorder. They concluded that there is not enough evidence to support one antidepressant over another and the therapy must be individualized considering adverse effects and drug interactions (17).

In terms of antiparkinsonian medication, monoamine oxidase type B inhibitors have demonstrated beneficial effects for patients with treatment-resistant depression and early therapy with rasagiline has been associated with neuroprotective effects (16).

To ensure correct diagnosis and establish a suitable therapy, several rating instruments are typically used: a) clinician-administered scales (like Montgomery-Asberg Depression Rating Scale, Hamilton Depression Scale and Young Mania Rating Scale) and b) self-assessment scales (like Zung Self-Rating Depression Scale, Patient Health Questionnaire, Beck Depression Inventory and Mood Disorder Questionnaire). These questionnaires are not specifically formulated for PD and they are combined with psychiatric/psychological interviews (18-20)**.**

Zung self-rating depression scale (ZSRDS) and Parkinson's disease

ZSRDS was developed by psychiatrist William W.K. Zung (1929-1992) and takes about 10 minutes to complete (21).

It is a 20-item scale, as shown in Table 1, with 4-point severity (from 1 = none, or a little of the time; to 4 = most, or all the time). 10 items show negative experience and 10 items show positive experience and are reverse scored (2, 5, 6, 11, 12, 14, 16, 17, 18 and 20). The interpretation of the result is: <50 = normal; 50-59 = minimal-

mild depression; 60-69 = moderate-marked depression; ≥70 = severe depression (22-24). Correlations with other depression scales include .68 with the Beck Depression Inventory and Mood Disorder Questionnaire and .41 with the Hamilton Depression Rating Scale (24).

ZSRDS evaluates psychological and somatic symptoms of depression and has been validated in many languages, including English, Italian, Japanese, Brazilian, Finnish and Chinese.

Somatic comorbidities confer some additional risk of morbidity in people with depression (25) thus it's important to identify somatic elements in patients with PD and depression and to allow appropriate treatment to improve patients' quality of life.

It has been extensively used to screen for and measure severity of depression in depressive patients with or without PD (26-30).

TABLE I

Zung Self-Rating Depression Scale (ZSRDS)

1. I feel down hearted and blue.
2. Morning is when I feel the best.
3. I have crying spells or feel like it.
4. I have trouble sleeping at night.
5. I eat as much as I used to.
6. I still enjoy sex.
7. I notice that I am losing weight.
8. I have trouble with constipation.
9. My heart beats faster than usual.
10. I get tired for no reason.
11. My mind is as clear as it used to be.
12. I find it easy to do the things I used to.
13. I am restless and can't keep still.
14. I feel hopeful about the future.
15. I am more irritable than usual.
16. I find it easy to make decisions.
17. I feel that I am useful and needed.
18. My life is pretty full.
19. I feel that others would be better off if I were
20. I still enjoy the things I used to do.

In a systematic literature review, Scrag *et al*. revealed that ZSRDS "has good internal consistency and test–retest reliability" and is more easily comprehended than other scales (e.g. Beck Depression Inventory and Mood Disorder Questionnaire). After analyzing several rating instruments, the authors concluded that ZSRDS is more suitable "for measurement of severity of depressive symptoms" than for the screening process (26).

However, recent years' research has successfully used ZSRDS for screening purposes.

In an electronic survey among patients diagnosed with PD, in patients with depression according to ZSRDS, almost 51% of them consider themselves not being depressed, and from those that do not have depression, almost 15% consider themselves depressed (31).

Olfactory dysfunction, anhedonia and depression have been evaluated in PD patients, and to assess the latter non-motor symptom of the disease the authors of the study relied on ZSRDS (32). Just as other researchers did when analyzing the correlation between depressive symptoms and nocturnal disturbances in PD patients (33,34).

This questionnaire also demonstrated its effectiveness in a recent study about the association of decreased serum brain-derived neurotrophic factor with depression in patients with PD (29).

Pramipexole is a non-ergot dopamine receptor agonist indicated for treating PD (both motor and non-motor symptoms). Different studies were conducted to assess the antidepressant effect of pramipexole, within which depressive symptoms have been measured by ZSRDS (35, 36).

One of the ergot alkaloids, bromocriptine is an agonist of dopamine receptors used in parkinsonism and endocrine disorders. Przuntek *et al*. developed two trials with concomitant administration of bromocriptine to levodopa therapy to quantify the beneficial impact of the combination therapy on the adverse effects of long term levodo-

pa treatment. Also, in this case ZSRDS has been used for measuring depressive symptoms (37, 38).

Chagas et al used it alongside other instruments, like the Patient Health Questionnaire-9 and the Geriatric. Depression Scale, and it proved to be a valid tool for screening depression in patients diagnosed with PD without dementia (30, 39).

The quality of life could influence the adherence of patients. Therefore, some questionnaires are used to identify and measure the adherence of PD patients with depression versus PD patients without depression (40).

CONCLUSIONS

Depression has a meaningful impact on patients' and their caregivers' lives, as well as on the health care system, therefore it is important to adequately screen for and correctly treat depression in patients affected by PD.

Although the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-V) from the American Psychiatric Association's is the golden standard for diagnosing depressive disorders, ZSRDS is efficient and easy to manipulate. Early recognition of depression is beneficial for the care of PD patients and the use of questionnaires can be useful to identify and to follow the severity of depression.

Conflict of interests. There are no conflicts of interest. All authors made equal contribution to the paper, to that of first authors.

EPIDEMIOLOGY AND CLINICAL CHARACTERISTICS IN DIABETIC PATIENTS WITH INVAZIVE DISEASE ASSISTED AT THE CLINICAL HOSPITAL OF INFECTIOUS DISEASES BETWEEN 2008-2010 (Abstract): Infections in the diabetic population can be severe and life threatning at least for two reasons: clinical signs are often torpid, masqued by chronical complications of diabetes leading to late recognition and medical adresability and also because of the inability to control established infection due to complex cell-mediated and humoral immunity deffects. The aim of the study was to evaluate the etiology, clinical features and outcome in diabetic patients with invazive disease. **Material and methods**: A retrospective study was conducted between January 2008 and December 2010 at The Clinical Hospital of Infectious Diseases Iaşi among 75 diabetic patients with sepsis of microbiologically confirmed etiology (positive cultures from normally sterile sites) and sepsis with clinically suspected etiology (positive cultures from pus). Cases with positive urocultures and coprocultures only, were excluded. **Results**: From 75 diabetics, 56% were males, 90,7% being over 50 years. Severe cases of sepsis (33/75, 44%) were associated more often with insulin-treated diabetes than non-insulin treated group (40% vs. 4%, $p<0,005$) probably because of multiple comorbidities associated as suggested by a high Charlson score (6,09 vs. 4,09, $p<0,05$). There were 64 cases with confirmed etiology and 11 cases with clinically suspected etiology. *Staphylococcus aureus* and *Escherichia coli* were the most common agents isolated, being involved in 16 (21,3%) cases each, followed by coagulase negative *Staphylococci* (14/18,66%), *Enterococcus* spp.(6/8%), group B *Streptococcus* (3/4%), *Streptococcus pneumoniae*, *Enterobacter* spp., *Salmonella* spp. (2/2,66% each), *Aerococcus viridans*, *Streptococcus equi*, *Klebsiella pneumoniae*, *Neisseria meningitidis*, *Sphyngomonas paucimobilis*, *Pseudomonas aeruginosa*, *Proteus mirabilis* (1/1,33%). Multiple septic disseminations occured in 17(22,6%) cases and meningeal involvment was doccumented in 10(15,6%) cases. Meticillin resistance was noted in 53,3% for invasive isolates of *S. aureus*. Among 16 invazive strains of *E. coli*, 25% were resistant to 3rd generation cephalosporins , 17% to ciprofloxacin and 6,6% to aminoglycosides and colimycin. There were no *E. coli* strains resistant to imipenem, piperacillin-tazobactam and aztreonam. The mean mortality rate was 14,66%. **Conclusions**: The high level of resistance of *S. aureus* and *E. coli* to commonly used antibiotics and meningeal involvement imposes a multidisciplinary approach of the diabetic patient. Proper knowledge of the pathogens involved in the potential invazive

diseases is an important tool for successful treatment with appropriate empirical broad-spectrum antimicrobial agents. **Key words:** DIABETIC INVAZIVE INFECTIONS, METICILLIN RESISTANCE, MENINGITIS, UROSEPSIS.

Persoanele cu diabet zaharat (DZ) pot contracta orice infecție ce afectează populația generală, dar, evoluția acesteia spre forme severe de sepsis are cel puțin două substraturi: imunitatea umorală şi celulară deficitară reprezintă un factor important în limitarea infecției iar manifestările clinice, adesea torpide, mascate de complicațiile cronice ale diabetului reprezintă un impediment în diagnosticul şi inițierea precoce a terapiei. Sepsisul sever asociat cu DZ constituie o cauză de morbiditate şi mortalitate ridicată, cetoacidoza diabetică fiind indusă de variate infecții în 28% din cazuri. Cunoaşterea agenților patogenilor implicați, cel mai frecvent, în infecțiile cu potențial invaziv favorizează o abordare terapeutică adecvată.

MATERIAL ŞI METODĂ

Pentru a efectua corelații clinico-epidemiologice asupra infecțiilor invazive la bolnavul diabetic am realizat un studiu retrospectiv în Spitalul Clinic de Boli Infecțioase "Sf. Parascheva" Iaşi în perioada ianuarie 2008-decembrie 2010, prin evaluarea foilor de observație şi a documentelor anexate. În studiu au fost incluşi 75 pacienți cu diabet zaharat internați cu diagnosticul principal de sepsis cu etiologie precizată (prin culturi pozitive din hemoculturi şi/sau alte produse biologice normal sterile) şi sepsis cu etiologie suspectată clinic (culturi pozitive din colecții purulente cu diferite localizări). Au fost excluse cazurile de sepsis cu etiologie neprecizată şi cele la care s-au obținut doar uroculturi şi coproculturi pozitive. Au fost evaluate datele demografice (vârstă, sex, mediu), perioada spitalizării, tipul diabetului, etiologia şi severitatea infecției. Pacienții diabetici au fost împărțiți în două loturi în relație cu gradul de severitate al sepsisului, conform criteriilor standard (10): sepsis a fost definit ca infecție suspectată sau dovedită însoțită de sindrom de răspuns inflamator sistemic (cel puțin 2 criterii –febră/hipotermie, tahicardie, tahipnee, leucocitoză/leucopenie). Sepsisul sever este definit ca sepsis cu disfuncție organică acută (insuficiență renală, insuficiență respiratorie, coagulare intravasculară diseminată sau şoc). Comorbiditățile au fost identificate şi calculate utilizând scorul Charlson (9). Produsele biologice obținute au fost prelucrate în laboratorul de bacteriologie prin examen direct, culturi, latex aglutinare. Testarea rezistenței la antibiotice a izolatelor bacteriene a fost realizată prin metoda standard difuzimetrică (CLSI) şi E-test. S-a constituit o bază de date în Excel care a fost prelucrată ulterior cu ajutorul programelor *SPSS 16.0* şi *Epi Info 3.5.1*. Variabilele studiate au fost analizate descriptiv şi analitic şi s-au considerat semnificative statistic valorile $p< 0,05$.

REZULTATE

În perioada studiată, din cei 75 de pacienți incluşi în studiu, 56% au fost de sex masculin, cu vârste cuprinse între 31 şi 83 ani, 90,7% având peste 50 ani.

Din 55 (73,3%) pacienți cu DZ insulino-tratat, antecedente de DZ tip 1 au fost documentate la 9,3%; DZ tip 2 insulinotratat 58,7%; 5,3% au necesitat conversia terapiei hipoglicemiante orale în insulinote-

rapie; 26,7% au fost pacienți cu DZ tip 2 tratați cu antidiabetice orale (ADO) (tab. I). Pe baza criteriilor de selecție a gradului de severitate al sepsisului au fost documentate 42 cazuri de sepsis şi 33 cazuri de sepsis sever şi/sau şoc septic, vârsta medie în sepsisul sever fiind mai mare (70,19 *vs.* 59,25; p<0,001). Nu s-au înregistrat diferențe semnificative din punct de vedere statistic între cele două grupuri legate de sexul şi mediul de proveniență al pacienților. În lotul de pacienți cu sepsis sever scorul de comorbiditate Charlson a fost mai mare (6,09 *vs.* 4,04; p<0,05).

Investigațiile microbiologice au confirmat etiologia la 64 cazuri de sepsis, majoritatea microorganismelor (82 tulpini) fiind identificate în hemoculturi (HC) sau concomitent din HC şi alte produse patologice (lichid cefalorahidian, puroi, urocultură). În 11 cazuri de sepsis cu etiologie suspectată clinic, agentul patogen a fost izolat din puroi provenit din diferite situsuri care au fost identificate ca poartă de intrare posibilă.

[a]Confirmare microbiologică prin culturi pozitive din HC/alte produse biogice normal sterile,
[b]culturi pozitive din puroi , IT=insulino-tratat

Dintre cazurile de sepsis cu etiologie certă, în 38 (59,3%) cazuri au fost implicate bacterii Gram pozitiv, 24 (37,5%) bacterii Gram negativ, 2 (3,1%) cazuri fiind cu etiologie mixtă. Pacienții cu sepsis cu *Staphylococcus aureus* au prezentat criterii de sepsis sever/şoc septic sau sepsis în 9 (14,06%) respectiv 4 (6,25%) cazuri.

Determinări multiple în cadrul sepsisului stafilococic au survenit la 7 pacienți. Pe lângă infecția cutanată (la 8 din 13 paci-

enţi) au fost obiectivate clinic şi paraclinic următoarele localizări: bronhopneumonie şi meningită (3), artrită, meningită şi epidurită (1), articulare (1), pneumonie şi pleurezie (1), bronhopneumonie (1). Stafilococi coagulază-negativ au fost izolaţi din HC la 12 pacienţi diabetici (4 cu determinare respiratorie, 7 doar cu bacteriemie).

TABELUL II

Etiologia infecţiilor şi determinările din cadrul sepsisului la pacienţii diabetici din lotul studiat

Microorganism (nr.tulpini)	Izolat din	Nr. cazuri sepsis sever/sepsis cu determinări						Total[3] ss/s	D

a=2 cazuri *S. aureus* –în asociere cu *E. coli*, respective Streptococ Grup B; b=3 cazuri *S. aureus* associate cu Streptococ Grup B, cu *K. oxytoca*, respectiv *Morganella morganii*; c=puroi otic; d=1 caz *E. coli* în asociere cu *M. morganii*; e=1 caz Enterobacter spp. în asociere cu *K. pneumoniae*; 1=HC; 2=HC+puroi; 3=HC+LCR+puroi; 4=LCR; 5=HC+UC; 6=puroi; 7=HC+LCR; s=sepsis; ss=sepsis sever; *= Nr.total cazuri ss/s etiologie cunoscută, Stafilococ coN=stafilococ coagulază negativ; Mg=meningită, D=decese.

Infecţii streptococice au fost identificate la 13 (20,31%) pacienţi. *S. pneumoniae* a fost izolat atât din HC cât şi din LCR la 2 pacienţi cu sepsis sever cu determinare meningiană. Infecţii invazive cu streptococ grup B au survenit în 3 (4,6%) cazuri. În 5

din cele 6 cazuri de sepsis cu enterococ tulpinile au fost izolate din HC, fără o poartă de intrare obiectivată clinic şi un caz a fost interpretat ca urosepsis. *Aerococcus viridans* a fost identificat în HC şi LCR la un singur caz de sepsis sever cu determinare meningiană, secundară unui episod de otomastoidită. *Streptococcus equi zooepidermidicus* a fost izolat din HC la un pacient cu sepsis.

Au fost izolate 18 tulpini de *E. coli*, 7 din acestea fiind implicate în urosepsis. Dintre cazurile de sepsis sever 5 au avut determinări multiple. Alte microorganisme Gram negativ identificate ca agent etiologic la pacientul diabetic cu meningită au fost *Klebsiella pneumoniae* şi *Neisseria meningitidis* grup B (câte un caz fiecare). În restul cazurilor de sepsis au fost identificate în HC, Salmonella grup B respectiv grup C (2), *Pseudomonas aeruginosa*, *Sphyngomonas paucimobillis*, *Proteus mirabilis* şi Enterobacter spp. (1) (tab. II).

Din cele 7 (9,33%) cazuri de sepsis de etiologie mixtă, cu punct de plecare cutanat, la doi pacienți cu sepsis sever s-au izolat *S. aureus* şi *E. coli* respectiv Streptococ grup B din HC şi puroi; la restul pacienților au fost identificate asocieri dintre *S.aureus* şi Streptococ grup B (1); *Klebsiella oxytoca* şi *Morganella morganii* (1), *K. pneumoniae* şi Enterobacter spp.(1), respectiv *E. coli* şi *M. morganii* (1).

DISCUȚII

Invazia sangvină poate fi determinată de variate specii bacteriene, dar în mod particular pacienții cu diabet sunt receptivi la agresiunea stafilococică cu o incidență de 8-36% (4). Într-un studiu condus de Artero et al. (6) pe o perioadă de 7 ani, au fost evaluate caracteristicile clinice şi microbiologice ale pacienților diabetici cu bacteriemie şi sepsis sever sau şoc septic, comparativ cu nondiabetici, spitalizați într-un serviciu de terapie intensivă. Bacteriemia de origine nosocomială s-a înregistrat frecvent la pacienți cu DZ având ca etiologie tulpini de stafilococi coagulază negativ (21.6%), *Acinetobacter baumannii* (15%), *Staphylococcus aureus* (11.6%), *Escherichia coli* (8.3%), *Enterococcus* spp. (8.3%). La pacienții cu infecții invazive cu diabet s-a constatat o prevalența crescută a sepsisului sever şi a şocului septic.

În studiul nostru majoritatea pacienților (73,3%) erau cu DZ tratat cu insulină, în această categorie fiind incluşi şi cei la care a fost necesară introducerea insulinei pentru controlul dezechilibrelor metabolice induse de episodul infecțios. Un numar semnificativ mai mare de cazuri de sepsis sever a fost diagnosticat la acest subgrup comparativ cu bolnavii diabetic tratați cu ADO (40% vs. 4%, $p<0,005$). Acest fapt este datorat în special comorbidităților multiple secundare diabetului sau a unor imunodepresii asociate DZ, după cum este sugerat de scorul Charlson (6,09 vs. 4,09, $p<0,05$).

Spectrul etiologic al sepsisului la pacienții diabetici incluşi în studiul nostru a fost caracterizat de preponderența stafilococului (40%), fiind incluse şi cazurile cu etiologie suspectată clinic. *S. aureus* a fost implicat în cele mai multe cazuri de sepsis sever, cu determinări multiple. Dintre tulpinile invazive, 8 din 15 (53,3%) au fost *S. aureus* meticilino-rezistent. Deşi numărul de cazuri studiate este mic şi nu pot fi făcute extrapolări la întreaga populație diabetică, este de remarcat faptul că, procentul de rezistență al *S. aureus* este mult mai mare decât valorile de 19,7%, raportate de EARSS-Net în 7 din 22 țări din Europa, tendințe în scădere în perioada 2002-2009 (11). Rezistența la meticilină a *S. aureus* a fost de 48-50% în cele 2 studii desfăşurate în regiunea de NE a României care au analizat caracteristicile

infecţiilor stafilococice în perioada 2006-2008 (13,14). Prevalenţa enterococilor rezistenţi la vancomicină variază în Europa de la 1-40% (12). În 5 (6,6%) cazuri de infecţii invazive a fost documentată etiologia cu *Enterococcus* spp., toate tulpinile fiind sensibile la vancomicină, două rezistente la ampicilină, trei la ciprofloxacină şi una, la ambele antibiotice.

Infecţiile cu streptococ grup B constituie un risc major pentru pacienţii cu DZ şi alte grupuri cu imunitate scăzută (nounăscuţi, gravide), având un spectru larg de manifestări clinice, de la infecţii cutanate necrozante la sindromul şocului toxic (2,3). Contrar datelor din literatură în studiul nostru au fost izolate doar 5 tulpini (6,09%) de streptococ grup B (4).

Bacteriemia cu bacili Gram negativ rezultă de obicei din infecţii ale tractului urinar, infecţii gastrointestinale, ale veziculei biliare sau la pacienţii spitalizaţi cu catetere intravenoase. La pacientul diabetic gangrenă sinergică şi pneumonia cu bacili Gram negativ sunt alte două manifestări clinice responsabile de diseminare hematogenă. În studiul nostru dintre infecţiile invazive determinate de bacterii Gram negativ, mai mult de jumătate (66,6%) au fost cauzate de *E. coli*. Din 16 cazuri de sepsis cu *E.coli,* 43,75% au avut originea în afecţiuni ale aparatului urinar. Referitor la sensibilitatea la antibiotice a tulpinilor de *E. coli* invazive se remarcă o rată a rezistenţei la cefalosporine de generaţia aIII-a de 25% (4/16), ciprofloxacină 17,64% (3/17) şi 6,66% (1/15) la aminoglicozide, respectiv colimicină (1/11). Doar o tulpină de *E. coli* invazivă a fost decelată cu betalactamaze cu spectru extins. Datele obţinute în studiul nostru sunt similare cu cele raportate de Popescu et al. (8) în cadrul unui studiu multicentric în România, referitor la fluoroquinolone, dar diferite în ceea ce priveşte rezistenţa la cefalosporinele de generaţia a 3-a (CG3), la pacienţii diabetici fiind constatată o rată a rezistenţei mai mare de 25% vs. 14,08%. Nu s-au decelat tulpini rezistente la imipenem, piperacilină-tazobactam şi aztreonam. În literatură este notată o sensibilitate în creştere la piperacilină-tazobactam şi nitrofurantoin (7,8).

Afectarea meningiană a fost documentată la 10 (15,6%) cazuri de sepsis sever. Agenţii etiologici implicaţi în meningită, la bolnavii diabetici din lotul studiat, au fost *S. aureus*, pneumococul, *A. viridians*, streptococul grup B, *E. coli*, *K. pneumoniae* şi meningococul. Evoluţia a fost nefavorabilă la 11 pacienţi, rata mortalităţii în populaţia diabetică fiind de 14,66%. Microorganismele implicate în evoluţia nefavorabilă au fost: *S. aureus* şi *E. coli* (3 cazuri), stafilococ coagulază negativ, *P. mirabilis*, streptococ grup B, *Enterococcus* spp. (câte un caz).

CONCLUZII

Majoritatea infecţiilor invazive la bolnavii diabetici internaţi în Spitalul Clinic de Boli Infecţioase (2008-2010) au survenit la cei insulino-trataţi, cazurile de sepsis sever având vârsta peste 70 ani. Etiologia sepsisului a fost dominată de *S. aureus* şi *E. coli*, determinări multiple, în cadrul sepsisului sever, fiind cauzate cel mai frecvent de etiologia stafilococică. Nivelul crescut al meticilino-rezistenţei (53,3%), rezistenţa în creştere la CG3 şi la fluorquinolone a bacililor Gram negativ, cât şi afectarea meningiană frecventă reprezintă un semnal de alarmă şi impun o abordare multidisciplinară a pacientului diabetic. Considerăm că sunt necesare studii extinse pentru optimizarea terapiei la această categorie de pacienţi pe baza cunoaşterii profilului de rezistenţă regională al germenilor implicaţi şi a particularităţilor evolutive comparativ cu pacienţii non-diabetici.

MULȚUMIRI

Studiul de față a fost posibil datorită finanțării în cadrul Grantului CNCSIS IDEI - nr. 2543 - U.M.F. „Gr. T. Popa" Iaşi.

ANTIBIOTIC PROPHYLAXIS CONSIDERING PATIENT OUTCOME FROM PERCUTANEOUS ENDOSCOPIC GASTROSTOMY

Mădălina-Paula Cosmulescu[1, 2], J. N. Russell[3]

1. Ph.D. student of "Gr.T.Popa"University of Medicine and Pharmacy, Iasi
2. North Cumbria University Hospitals NHS Trust, U.K
3. West Cumberland Hospital, Whitehaven, U.K

ANTIBIOTIC PROPHYLAXIS CONSIDERING PATIENT OUTCOME FROM PERCUTANEOUS ENDOSCOPIC GASTROSTOMY (Abstract): **Objectives:** The main indications for PEG insertions are the following: stroke/CVA/diffuse cerebral vascular disease, neurological conditions, e.g. head injury, motor neurone disease, Multiple Sclerosis etc. Peristomal infection can sometimes complicate PEG placement. Antibiotics, either prophylaxis or concurrent, can reduce the incidence of peristomal wound infection after PEG placement. **Material and method**: Seventy five patients outcome from Percutaneous Endoscopic Gastrostomy (PEG) were analysed in the period: September 1999 and October 2007 to the West Cumberland Hospital, Whitehaven (WCH) United Kingdom. This paper was done to evaluate the practice in WCH and the outcome has helped us to implement the changes successfully to conform to the guidelines set out by the British Association of Gastroenterologists. Our main objectives were to evaluate the antibiotic prophylaxis, the procedure and post procedure complications and the deaths after PEG tube insertion. **Conclusions**: No immediate procedure complications; Infection was the most common postoperative complication; Antibiotics, either prophylaxis or concurrent, reduce the incidence of peristomal wound infection after PEG placement; Early PEG placement facilitates their transfer to a non-acute care environment. **Key words:** PERCUTANEOUS ENDOSCOPIC GASTROSTOMY, ANTIBIOTIC PROPHYLAXIS.

Percutaneous Endoscopic Gastrostomy (PEG) was first described in 1980. This descriptive study was initially conducted in 75 patients, who have undergone PEG tube placement during September 1999 and October 2007 with an overall average of 70 years of age. Medical records were analysed a well as getting ourselves familiar with various local and national guidelines for PEG insertion and removal.

OBJECTIVES

The main indications for PEG insertions are the following: stroke/CVA/diffuse cerebral vascular disease, neurological conditions, e.g. head injury, motor neurone disease, Multiple Sclerosis, cerebral palsy, myotonic dystrophy, head and neck malignancy, gut dysmotility, oesophageal involvement in AIDS, psychiatric patients with eating disorders, therapeutic, e.g. tethering of gastric volvulus. Peristomal infection can sometimes complicate PEG placement. Antibiotics, either prophylaxis or concurrent, can reduce the incidence of peristomal wound infection after PEG

placement (1,2,3).

RESULTS

Figure **1-a** presents antibiotic prophylaxis given at time of PEG procedure for 62 patients (82%), and if no antibiotic treatment already in use for the seven patients (8%) (fig.1-b). All patients should receive prophylactic antibiotics before the procedure, such as: 1,2g Co-amoxyclav (Augmentin) IV, or 1.5g Cefuroxime (penicillin allergy) (fig. 2).

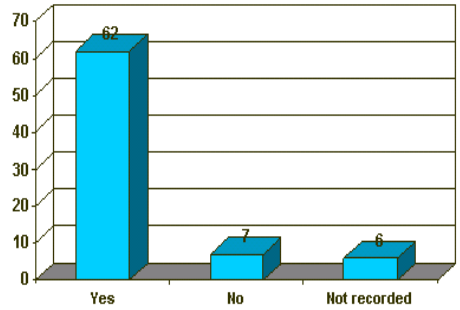

Fig.1-a Antibiotic prophylaxis given at time of procedure.

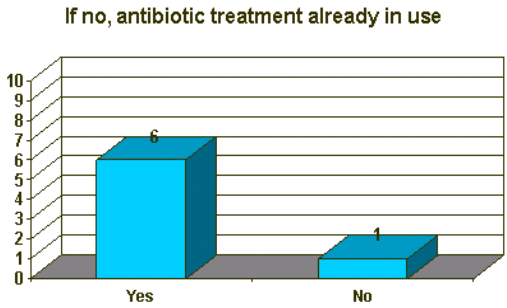

Fig.1-b If no, antibiotic treatment already in use.

Revised patients received the following antibiotics: Co-amoxyclav (Augmentin) IV for 59 patients, Cefuroxime for 3 patients, Teicoplanin for 2 patients, 1 patient received Gentamicin and for 9 patients had no antibiotics administered (fig. 2).

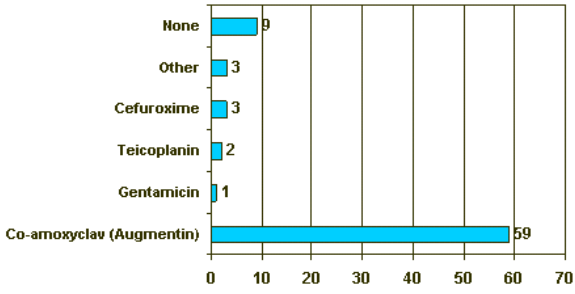

Fig.2 Antibiotics given.

All patients require IV access and they should be kept NBM (Nil by mouth) prior to the procedure. Recent U&Es, FBCs, full clotting results (abnormal or no result will lead to cancellation of the procedure for that day). Medication or therapies used during the PEG procedure are: Xilocaine throat spray, Midazolam and Buscopan (fig. 3).

Antibiotic prophylaxis is to be recommended as a general measure in Percutaneous Endoscopic Gastrostomy (7,8). PEG tubes were inserted by specialized physicians in all cases. One patient required reversal agent after sedation, 51 patients (68%) do not required reversal agent and 23 patients (31%) were not recorded (fig. 4**).**

Complications were classified as severe (bleeding, peritonitis, tube dislocation which needed intervention) and in non-

severe (local infection, pain which were treated by conventional means) (9,10). No cases of bleeding or failure were recorded during PEG procedure for all the patients included in the present study (fig. 5).

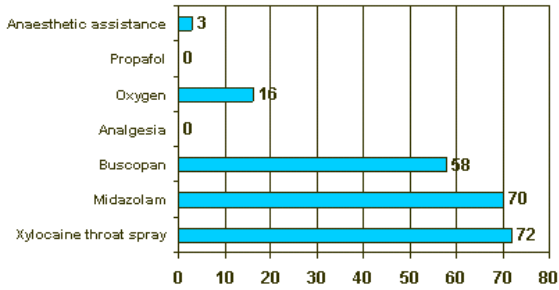

Fig. 3. Medication/therapies used during procedure

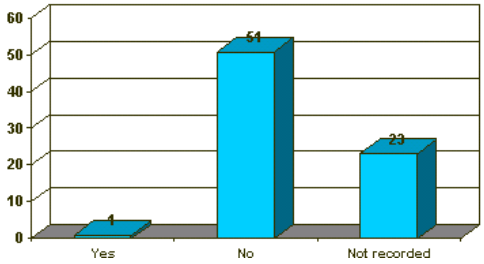

Fig. 4. Reversal agent used

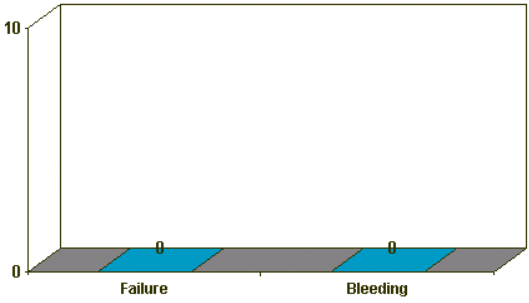

Fig. 5. Procedural complications

LONG TERM COMPLICATIONS

Infection at the insertion site, oesophageal reflux resulting in aspiration pneumonia, tube occlusion, accidental or intentional removal of PEG tube by the patient, gastric perforation, gastrocolic fistula, internal leakage, dehiscence, peritonitis, subcutaneous abscess, buried bumper syndrome (migration of the internal bumper of the PEG tube into the gastric or abdominal wall) are considered the most common complications (11,12,13).

In our analysis the post procedure complications within 30 days (fig. 6**)** showed an overall complication rate of 21%, including chest infection for 9 patients (12%), wound site infection for 4 patients (5%), 1 patient (1.4%) peritonitis

and 2 patients haemorrhage (2.6%). Eight patients presented multiple co-morbidities. Indications for PEG procedure should therefore be carefully reviewed. The rate of complications seems to be determined by post procedure care rather than by the indication or the procedure itself (14, 15,16). Figure 7 shows the number of patients who required treatment with antibiotics.

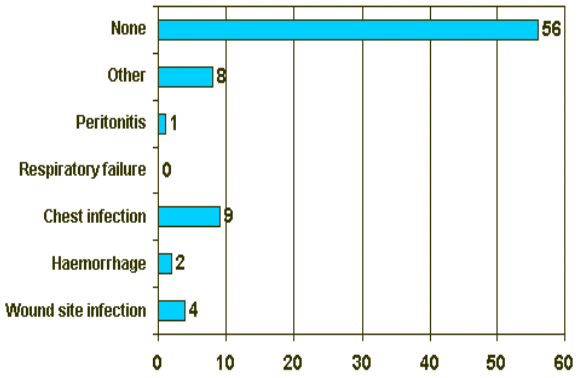

Fig. 6. Post procedure complications within 30 days

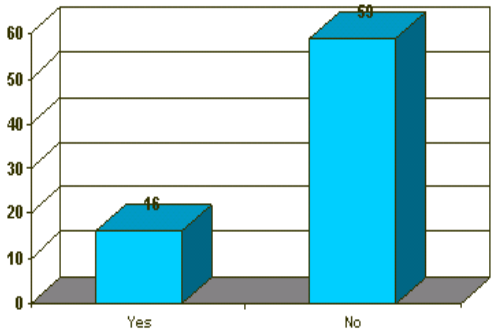

Fig. 7. Post procedure information; Patients receive antibiotic treatment

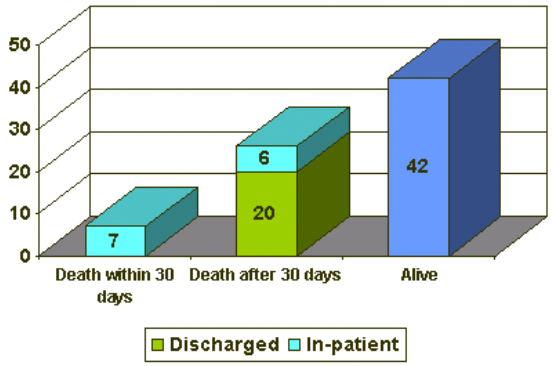

Fig. 8. Post procedure information; Outcome

The post procedure information regarding the outcome of the patients is presented in figure 8. Only 7 patients (9%) died within 30 days, 26 patients (34%) died after 30 days, and 42 patients (57%) are still alive. Non-severe complications occurred in 57% of the cases and severe complications were recorded in 9% of the cases.

All severe complications developed within 30 days led to the death of 7 patients (9%) are presented in fig.8. Death was due to Cardiovascular disease, Cardiac impairment for 5 patients, severe renal impairment disease for 2 patients, Alzheimer severe dementia for 2 patients, COPD for 3 patients, and other diseases for 6 patients (fig. 9).

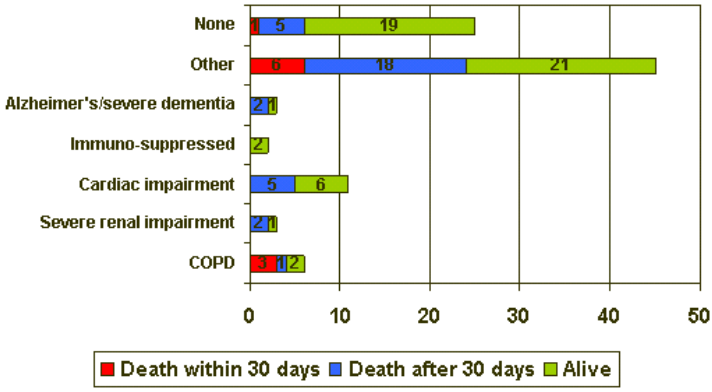

Fig. 9. Post procedure information; Co-morbidities

Mortality and morbidity rates after PEG tube insertion are not insignificant for the majority of the cases but, more observations and research on a larger number of patients susceptible to PEG method are needed as well as a multidisciplinary team assessment must be performed on all patients being referred for PEG tube insertion (17).

RECOMANDATION TO PEG PROTOCOL: Establishing consent in all patients pre operatively, achieve 100% antibiotic prophylaxis and follow the Trust PEG protocol.

CONTRAINDICATIONS TO PEG PROTOCOLS: Current chest infection, ascites, portal hypertension (relative contraindication), peritonitis, bleeding disorders (relative contra-indication), active gastric ulcer (relative contra-indication), gastro-oesophageal reflux with risk of aspiration (relative contra-indication), disseminated intra-abdominal malignancy, pregnancy (relative contra-indication).

CONCLUSIONS

No immediate procedure complications.

Antibiotics, either prophylaxis or concurrent, reduce the incidence of peristomal wound infection after PEG placement.

24% of patients had PEGs removed.

Mortality within 30 days of procedure was less than the national average of 10%.

90.5% of patients received antibiotic prophylaxis, either prior or at time of procedure.

Average patient's age on PEG insertion was 70 years.

More research needs to be undertaken to provide evidence so improved guidelines can be developed in this area.

Minor postoperative complications not requiring intervention occurred at 9.5% of patients, and major complications in 20 % of studied cases.

Infection was the most common post-operative complication.

No patient died as a direct result of the procedure.

Early PEG placement facilitates their transfer to a non-acute care environment.

PIERRE MARIE-SAINTON CLEIDOCRANIAL DYSPLASIA (Abstract): The paper presents a family with hereditary transmitted Marie-Sainton dysplasia affecting the father and his both children. This is a rare syndrome presenting an autosomal pattern of inheritance, characterized by a generalized defect in both membranous and endochondral bone formation resulting in clavicular aplasia, delayed ossification of the fontanelles and the sutures of the skull and prolonged retention of deciduous dentition with delayed eruption of the permanent teeth. The diagnosis is suggested by more or less complete clinical picture and confirmed by multiple radiological explorations (skull, thorax, spinal column, pelvis) and genetical examination. The genetic mutation for cleidocranial dysplasia (CCD) is found on chromosome six and is called CBFA1 (short for core biding factor a1 or RUNX2) and is the only gene known to be associated with CCD. The normal version of CBFA1 acts to induce osteoblasts which are the type of cells that lay down bone. Although associated psychosocial disorders can occur, the prognosis and life expectancy of this condition are favorable being conditioned however by the complexity of orthodontic procedures which are determinant for these patients life quality. **Key words:** CLEIDOCRANIAL DYSPLASIA, GENETICS, AUTOSOMAL DOMINANT, RADIOLOGY, ORTHODONTIC

Displazia (disostoza) cleidocraniană este o boală rară cu transmitere autosomal-dominantă, descoperită de obicei de la naştere în principal pe baza defectului de osificare a bolții craniene (1). Diagnosticul clinic este susținut de examenele radiologice (craniu, coloană, torace, pelvis, oase lungi, ortopantograma) şi confirmat prin efectuarea cariotipului care identifică mutații ale genei CBFA1 (1). Afecțiunea are un prognostic favorabil, intelectul nu este afectat, tulburările de creştere sunt moderate iar anomaliile claviculare nu sunt invalidante; supravegherea şi tratamentul stomatologic adecvat sunt însă esențiale (2). Prezentăm cazul unei familii cu doi copii, o fetiță de 3 ani şi un băiețel de 1 an şi 8 luni, diagnosticați în clinica noastră cu disostoză cleidocraniană Marie-Sainton. Cazurile celor doi pacienți însumează modificări osoase multiple, consecință a defectelor de osificare membranoasă cât şi cartilaginoasă, cu repercusiuni secundare asupra dezvoltării scheletice.

PREZENTAREA CAZULUI

Copiii M.A şi M.G se internează în clinică pentru investigații, suspicionându-se un rahitism carențial comun. Din AHC reiese că tatăl copiilor a prezentat fractură bilaterală de claviculă la naştere, închidere tardivă a fontanelei anterioare (la vârsta de 5 ani), deficit statural comparativ cu fratele său geamăn precum şi modificări importante ale dentiției definitive pentru care a urmat numeroase intervenții chirurgicale în adolescență. Alte AHC semnificative sunt cazul bunicului patern cu hipoplazie bilaterală de claviculă şi deficit statural cât şi cazul unei verişoare primare (de asemenea pe linie paternă) în vârstă de 13 ani cu spina bifida sacrată, scolioză dorsală, dinți supranumerari anormal implantați. APP relevă că ambii copii au prezentat fractură bilaterală de claviculă la naştere.

Din examenul clinic reținem că fetița prezintă la 3 ani: G=12kg (-1,6 DS), T=90 cm (-0,81 DS), PCr=49,8cm (+0,75 DS) iar băiatul, la 1 an şi 8 luni, G=8800g (-2,88DS), T=76,5cm (-2,07 DS) iar PCr= 48,2cm (+0,16 DS). Modificările de la nivelul craniului şi faciesului la ambii pacienți: discretă dismorfie facială cu hipertelorism, urechi mai jos inserate, fante palpebrale uşor antimongoloide (doar la băiat); fontanelele anterioare deschise, cu dimensiuni 3/3cm la fetiță respectiv 2/2cm la băiat. La tatăl copiilor am observat un prognatism pseudomandibular, consecință a dezvoltării insuficiente a maxilarului care este scurt în raport cu mandibula, urechi jos implantate precum şi proteza totală (fig. 1, 2, 3). Fetița prezintă dentiție temporară completă iar băiatul doar incisivii centrali şi laterali, atât superiori cât şi inferiori. La nivelul trunchiului se remarcă clavicule deformate bilateral, hipoplazice, umeri înguşti, stern înfundat şi torace asimetric evazat la baze (fig. 4)..

Fig. 1. M.G, 3 ani - umeri înguşti, claviculă deformată

Fig. 2. M.A, 1 an 8 luni - hipertelorism

Fig. 3.M.I,35 ani-prognatism pseudomandibular

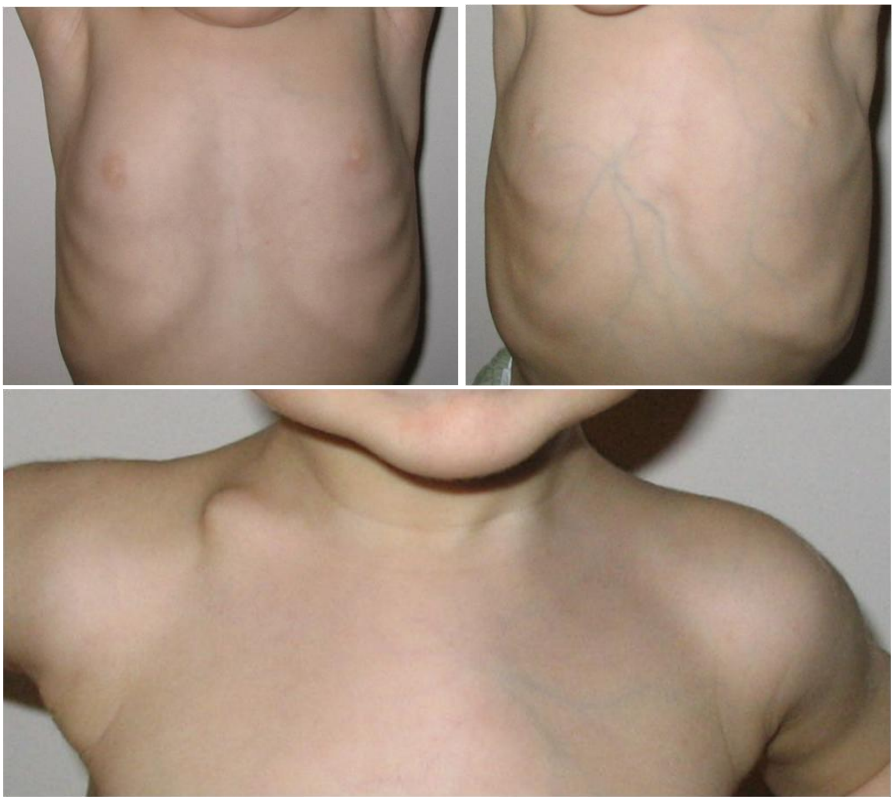

Fig. 4. M.G, 3 ani, M.A, 1 an 8 luni - stern înfundat, torace "în clopot", claviculă deformată

Testele de laborator au arătat doar uşoară anemie feriprivă la amândoi copiii (Hb= 10,2-10,9 mg/dl, Fe=48-56 µg/dl) şi valori la limita inferioară a normalului pentru calcemie şi fosfatemie (Ca=8-8,2 mg/dl, P=3,4-3,6 mg/dl); în acelaşi timp fosfatazele alcaline au fost în limite normale (F alc=369-543U/l). S-au exclus astfel un rahitism carențial comun precum şi o hipofosfatazemie congenitală de tip infantil.

Examinarea radiologică a inclus radiografii de craniu, coloană vertebrală, torace, pumn şi pelvis. Pe radiografiile de craniu (față şi profil) ale ambilor copii se remarcă proeminența boselor frontale, FA deschisă, prezența la nivelul osului occipital de numeroase fragmente osoase şi oasele masivului facial hipoplazice (fig. 5).

Radiografiile toracice relevă prezența a câte două fragmente de claviculă bilateral (fig. 6).

Pe radiografiile de pumn se observă întârziere în dezvoltarea nucleilor carpieni(fig. 7) iar pe cele de pelvis oasele iliace apar hipoplazice cu aripi etalate (fig. 8).

S-a efectuat examenul genetic (inclusiv cariotipul) la ambii pacienți si la tatăl acestora,care confirmă diagnosticul de displazie cleidocraniană Pierre Marie-Sainton pe baza elementelor clinice şi modificărilor radiologice sugestive. În prezent copiii sunt în evidența unei clinici de pediatrie din Spania, unde locuiesc împreună cu familia.

DISCUȚII

Disostoza cleidocraniană, posibil întâlnită şi la omul de Neanderthal a fost descrisă prima data sub acest nume în 1898 de Pierre Marie şi Pierre Sainton, dar observată încă din 1765 de Martin şi în 1871 de Scheuthauer. Soule şi Jackson au raportat alte cazuri în anul 1946 (3,4). Fiind vorba de o tulburare de creştere mai mult decât de o disostoză, este preferabil de a se denumi această maladie *displazie cleidocraniană* (Pierre Maroteaux) (4). Frecvența bolii a fost raportată ca fiind de 1/1000000, cu afectarea în egală măsură a ambelor sexe şi fără a exista o predispoziție etnică. Boala se transmite autosomal dominant în 2/3 din cazuri, în rest fiind vorba de mutații spontane. Gena mutantă implicată în producerea afecțiunii se găseşte pe cromosomul 6 şi se numeşte CBFA1 (prescurtarea pentru core binding factor a1 sau RUNX2); în mod normal aceasta stimulează producerea osteoblaştilor şi se pare că acționează nu numai în perioada embrionară dar este implicată şi în dezvoltarea fetală şi în cea postnatală (1). Aceasta afecțiune face parte din grupul osteocondrodisplaziilor care cuprinde anomalii de dezvoltare ale creşterii osului şi cartilajelor. Displazia cleidocraniană reprezintă prototipul tulburărilor în dezvoltarea oaselor craniului şi a claviculei. Diagnosticul clinic se bazează pe asocierea dintre hipoplazia claviculei, fontanela anterioară deschisă şi dinți supranumerari (1). Rareori clavicula poate fi absentă în totalitate; în general osul este redus la una sau două jumătăți rudimentare care se articulează cu sternul şi acromionul iar porțiunea sa mediană este deficientă. În formele grave umerii se apropie pe linia mediană. Frecvent modificările sunt asimetrice. Muşchii care se inseră pe claviculă pot avea o dezvoltare insuficientă. La nivelul craniului osificarea defectuoasă interesează fontanelele care sunt largi iar suturile dehiscente; la unii indivizi acestea pot să nu se închidă niciodată. Dezvoltarea excesivă a boselor frontale, parietale şi occipitale poate da craniului un aspect globulos (1,6). Frecvent se descriu şi oase vorniene. Anomaliile de dezvoltare la nivelul masivului facial (maxilarele, oasele nazale şi lacrimale) pot fi însoțite de absența sinusurilor (7). Mai pot apare micro/retrognația şi malocluzia. Bolta palatină este înaltă şi se descriu fante atât la nivelul palatului dur cât şi al celui moale (7). Copiii prezintă hipertelorism, deprimarea rădăcinii nasului şi glosoptoză. Modificările dentiției apar în până la 94% dintre cazuri. Formarea şi maturarea dentiției temporare sunt normale, existând însă un deficit de resorbție a laminei dentare ceea ce duce la persistența acesteia până în viața de adult, formarea de dinți supranumerari, întârziere în erupția dentiției definitive, hipodonție şi formarea de chisturi odontogene (8)**.** Extragerea dentiției temporare nu duce la erupția celei permanente (9). Dinții supranumerari apar cu o frecvență de 5% în regiunea molară şi de 22% în zona incisivilor maxilari superiori. Aceştia sunt impactați, ectopici şi prezintă anomalii ale coroanei şi rădăcinilor. Au existat cazuri la care s-au identificat până la 63 de asemenea dinți (7-9). Cutia toracică este deformată în pâlnie cu coaste verticalizate, modificări ce pot conduce la tulburări respiratorii iar la nivelul coloanei se descriu scolioza (uneori severă), malformații sacro-coccigiene şi spina bifida. Pot apare şi tulburări în osificarea oaselor ischio-pubiene şi iliace, uneori

simfiza pubiană este deschisă. Morfologia membrelor este puțin modificată dar deformările tip genu valgum sau platfus sunt frecvente; se mai întâlnesc degete scurtate și unghii rotunjite. Mâinile prezintă falanga distală scurtată, cu epifize masive și brahimezo-falanga degetului V (2,6). Modificări similare se observă și la plante. Talia este redusă, inclusiv în comparație cu cea a fraților/surorilor neafectați de boală (la băieți diferențe de 7,5 cm iar la fete de 15 cm) (1). Intelectul este normal. Ca probleme de patologie asociate se descriu sinuzitele recurente și alte IACRS, otite recidivante care pot conduce la pierderea auzului, retard motor mediu la copiii între 1 și 6 ani iar la fete distocii mecanice de bazin care impun, la vârsta maturității, nașterea prin cezariană (1). Diagnosticul este sugerat de anamneza familială pozitivă (se impune o anchetă amănunțită pentru ultimele trei generații) și de elementele clinice, fiind confirmat prin examene radiologice (radiografii de craniu, torace, coloană vertebrală, pelvis, oase lungi) și prin efectuarea cariotipului (totuși mutațiile genei RUNX2 sunt detectate doar în 60-70% dintre cazuri, de aceea un rezultat normal nu exclude diagnosticul) (1,5,6). Diagnosticul diferențial trebuie să excludă alte dezordini genetice dar cu transmitere autosomal recesivă și cu manifestari specifice ca sindroamele Crane Heise, Yunis Varon sau Maroteaux Lamy (picno-disostoza).

Managementul displaziei cleidocraniene include sfatul genetic în perspectiva unei viitoare sarcini pentru familiile în care cel puțin un membru este afectat, terapia susținută a sinuzitelor și otitelor recidivante (care poate include și montarea unor tuburi de timpanostomie), protecția cutiei craniene, suplimentare cu calciu și vitamina D în cazul în care densitatea osoasă este redusă și profilaxia precoce a osteoporozei.

Tratamentul stomatologic este esențial, se efectuează în echipă multidisciplinară pe parcursul mai multor ani și include extracția dinților supranumerari, expunerea dinților impactați sau încă neerupți pentru a forța erupția ortodontică, alinierea ortodontică în ocluzie, înlocuirea prin lucrări gnato-protetice a dinților absenți, măsuri de corecție estetică a anomaliilor de formă dentară și deseori chirurgie ortognatică a discrepanțelor scheletice maxilare (1,10, 11,12).

CONCLUZII

Cazul prezentat ilustrează atât modalitatea de transmitere a displaziei cleido-craniene cât și modificările clinico-radiologice tipice întâlnite în această afecțiune.

Diagnosticul tardiv în cazul tatălui a avut drept consecință modificări invalidante ale dentiției și necesitatea protezării totale; în același timp sfatul genetic ar fi putut preveni afectarea ambilor frați de către această maladie.

În cazul copiilor diagnosticul precoce va permite inițierea în timp util a tratamentului stomatologic complex.

Considerăm că închiderea tardivă a fontanelei anterioare este un semn clinic valoros, care poate orienta către diagnosticul de displazie cleidocraniană, mai ales în prezența unui tablou biologic normal; în astfel de cazuri se va prefera o evaluare radiologică minuțioasă și orientarea către un serviciu de genetică clinică.

NOUTĂȚI

MODULAREA EXPRESIEI GENELOR DE VIRULENTA ALE *STAPHYLOCOCCUS AUREUS* DE CATRE ANTIBIOTICE BETA-LACTAMICE UTILIZATE IN CONCENTRATII SUBINHIBITORII

Stimularea expresiei genelor de virulență de către concentrații subinhibitorii ale anumitor antibiotice poate modifica evoluția infecției şi poate face ca terapia antimicrobiană să devină ineficientă. Investigarea efectelor concentrațiilor subinhibitorii ale antibioticelor care inhibă sinteza peretelui bacterian asupra expresiei genelor de virulență şi asupra producerii biofilmului la *Staphylococcus aureus* a fost realizată folosind metode difuzimetrice şi prin real time PCR cantitativ. Expresia genelor *spa* (*staphylococcal protein* A) şi *luk*E a fost stimulată de concentrații subinhibitorii de penicilină şi cefalotin, în timp ce expresia *agr* RNAIII (*accessory gene regulator*) nu a fost afectată. De asemenea, s-a observat producerea unui biofilm mai dens în prezența unor concentrații subinhibitorii de cefalotin (Subrt N, Mesak LR, Davies J. Modulation of virulence gene expression by cell wall active antibiotics in *Staphylococcus aureus. J Antimicrob Chemother*. 2011; 66: 979-84).

POSSIBLE RELEVANCE OF PHYSICAL EXERCISING IN ALZHEIMER'S DISEASE AND OTHER DEMENTIAS (Abstract): The benefits of consistent exercising, either cardiovascular, strength training or a combination of both, have been recently shown in neuropsychiatric patients such as Alzheimer's disease and other dementia cases. In this way, an inverse relationship between cognitive impairment commonly observed in demented patients and cardiovascular fitness was demonstrated in a multitude of recent studies, which will be described and analyzed here. Moreover, several related features such as the relevance of oxidative stress, obesity and inflammation are discussed in this context. In addition, intensive muscle training was shown to be particularly effective leading to improved postural and motor response, and therefore reducing the motor impairments effects in dementia patients. Thus, the current trend in prevention is to support physical activity to delay dementia onset, knowing that physical exercising may be crucial in slowing or stopping the motor and general abilities decline in these patients. **Keywords:** ALZHEIMER'S DISEASE, MILD COGNITIVE IMPAIRMENT, MEMORY LOSS, EXERCISING, CARDIOVASCULAR TRAINING, STRENGTH TRAINING.

Alzheimer's disease (AD) is a form of dementia in which the memory decline is extremely severe causing distress and everyday cognitive performance impairment. Besides memory deficits, other cognitive impairments are exhibited by some individuals, but with no frequency or severity that would indicate a new specific feature caught in dementia diagnostic. In incipient stages, most of the AD patients develop very mild dementia or mild cognitive impairment (MCI) ("cognitively impaired no dementia") (1, 2).

AD is the most common form of dementia among the elders. This condition is characterized by the progressive cognitive function decline and is receiving an increased attention in the current literature and social aspects of life (3-5). Due to the intense psychological and physiological symptomatology, a detrimental global impact has been observed. Presently, an estimation counts more that 36 million patients worldwide and a prediction for the year

2015 even triples the number of cases (6).

In addition, AD is a complex, multifactorial, heterogeneous mental illness, which is characterized by an age-dependent loss of memory and an impairment of multiple cognitive functions. Molecularly, AD is associated with the presence of intracellular neurofibrillary tangles and extracellular beta-amyloid plaques which leads to neuronal subpopulations loss, mitochondrial oxidative damage, some specific genetic deficiencies, synaptic loss and the proliferation of reactive astrocytes and microglia (6).

As mentioned, recent studies support physical activity as an important preventive factor against AD onset. Furthermore, they are stating that physical exercising could be crucial for the maintenance or for slowing down the decline of optimal functional ability levels in these patients. However, small evidence points to a personalized exercise scheduled tasks which would help dementia patients.

In this way, as we will show in this mini-review, aerobic exercise is encouraged by therapists considering its role in angiogenesis neurotrophic factors release (increases in cerebral blood flow and cerebral plasticity).

Thus, the purpose of this investigation was to review the benefits of consistent exercising, either cardiovascular training, strength training or combinations of both in AD. Considering that an inverse relationship between cognitive impairment and cardiovascular fitness was demonstrated in several encouraging studies, and also that strength training was shown to be particularly effective for improving postural and motor functioning leading to reduced risk of motor failure in AD subjects, we will further discuss the possible implications and several presumed mechanisms of physical exercise on cognitive performance.

Cardiovascular exercises and Alzheimer's disease

Currently, studies regarding general fitness and cognitive impairments have focused on the effects of cardiorespiratory exercise on symptoms associated with these conditions (7). This may be due to the inverse relationship between cognitive impairment and cardiovascular fitness proven in some studies (7, 8).

For example, Burns *et al.* demonstrated that subjects who had higher levels of cardiorespiratory fitness (VO_2 peak) displayed lower levels of brain atrophy (8).

In addition, some randomized control trials have evaluated if cardiorespiratory exercise has a beneficial effect on cognitive response in older patients with AD. In this way, Lautenschlager *et al.* (9) conducted an intervention in elderly patients for a period of 6 months followed by 18 months follow-up period, but no significant difference in cognitive responses was found. We also must mention that Alzheimer Disease Assessment Scale-Cognitive subscale (ADAS-Cog) and ADL - was used for cognitive response assessment and compared between the exercise group and the control group.

On the contrary, Baker *et al.* (10) found that improved cardiovascular fitness was accompanied by an increased efficiency in activities, such as executive control processing, multitasking, information processing performances and selective attention when they evaluated the effect of a 6-month cardiorespiratory exercise intervention. However, when the results were adjusted for sex, a significant difference occurred only in women with increased oxygen consumption (VO_2 peak) and im-

provements in cognitive activities.

The effects of general fitness on cognitive performances may be also discussed in terms of the relationship between body mass index (BMI), age and oxidative stress (11). In this way, convincing evidence demonstrated that oxidative stress is a prominent feature in AD linking oxidative stress to the development of neuronal death and neural dysfunction, which suggests a key pathogenic role for oxidative stress in AD (12).

In addition, the evidence for the role of total adiposity, usually measured clinically as body mass index, and central adiposity, in AD is constantly increasing (11). This topic is of enormous public health importance given the global epidemic of obesity and its consequences.

Even more accumulating evidence is also suggesting that changes in lifestyle factors such as increasing physical activity will decrease the risk of developing dementia in later life (13). Other studies also showed reduced rate of age-related cognitive decline, decreased risk of incident dementia or AD in individuals who exercise regularly (14).

In this way, there are some possible explanations for the inequality between men and women regarding cognitive improvement in association with exercise. For example, it is speculated that estrogens may have a neuroprotective effect because many women after menopause are on hormone replacement therapy (15).

Therefore, regardless of biological gender, the conclusion is that cardiorespiratory training may be critical for a patient with AD, especially in the initial phase of the disease (16).

In addition, recently Middleton *et al.* (17) found that women which reported being physically active at any point over their life course had a lower likelihood of cognitive impairment in later life.

Molecular aspects for the association between physical exercise and ad care

As already mentioned, oxidative stress is a major factor associated with the development and progression of AD and other forms of dementia (2). A large part of data suggests that free radical oxidative damage-particularly of neuronal lipids, nucleic acids, and proteins are extensively implicated in the brain pathology of AD patients (12).

Increased oxidative stress is thought to result in the generation of free radicals and ROS, which is reported to be released by microglia activated by amyloid beta (18). When compared to other organs, the brain has been found to be more vulnerable to oxidative stress due to its high lipid content, its relatively high oxygen metabolism, and its low level of antioxidant defenses (19).

Also, some cytokines are potent stimulators to produce reactive oxygen and nitrogen by macrophages and monocytes and therefore a rise in the concentration of cytokines could be responsible for increased oxidative stress.

Even more, obesity increases the mechanical load and myocardial metabolism and therefore oxygen consumption is increased. Of course, one negative consequence of increased oxygen consumption is the production of ROS as superoxide, hydroxyl radical, and hydrogen peroxide derived from the increase in mitochondrial respiration and from the loss of electrons produced in the electron transport chain, resulting in the formation of superoxide radical (20).

Lately our group also demonstrated that oxidative stress is importantly related with

exercising (21-23) and that increased oxidative stress status may be characteristic to AD and MCI patients (2, 12).

Moreover, as one of the main factors that lead to obesity is the lack of sustained physical effort alongside some harmful alimentary habits (24), there is an increased awareness also on the relationship between obesity, oxidative stress and cognition.

In this way, the association between obesity and oxidative stress appears to be due to the presence of excessive adipose tissue itself, because adipocytes and preadipocytes have been identified as a source of proinflammatory cytokines, including TNF-α, IL-1, and IL-6, as sometimes obesity is considered a state of chronic inflammation. In fact, concerning the cardiorespiratory exercises there are many contradictory results regarding the connections that might exist between exercising and oxidative stress. A possible explanation for these different results could be differences that might appear between trained and untrained subjects. This theory was proven so far on rats. Senturk *et al*. demonstrated that exercise-induced oxidative stress affects erythrocytes in sedentary rats, but not in exercise-trained rats (25).

In this context, we could mention here the connection between inflammation and disorders such as rheumatoid myositis or psoriatic arthritis (26, 27), which were previously described as having some degree of correlation with AD, as demonstrated even by some previous Nature group publications (28-31).

Thus, concluding, it seems that over the years cardiorespiratory fitness development has received extensive research interest. Common methods for developing cardiorespiratory fitness are running, cycling, swimming, or brisk walking.

Strength training and AD management

For many years strength training potential positive effect on cognitive impairment was disregarded. However, since AD is associated with low muscle mass and strength (32), muscle strength and power training could in fact be crucial for AD patients.

In addition, balance training has been shown to improve the postural abilities of subjects which were moderately-to-severely affected by AD, and so reduce the risk of falling at a later stage of the disease (33).

In this way, a complete exercise training (including balance training, aerobic exercise and strength training) was shown to be particularly effective for improving postural and motor functioning and reducing the risk of falling in AD subjects (34).

Another randomized controlled trial, which was performed in elders' residential institutions in France, investigated the effect of an exercise program on the ability of AD patients to perform activities of daily living, physical performance, behavioral disturbances and depression. In this study, Rolland *et al.* (35) conducted a complete exercise program for 12 months with 1 hour of exercise twice a week, training program that included walking exercise, muscle strength, balance and flexibility tasks, while the control group received only traditional health care. Thus, at the end of the study the intervention group performed significantly better in the 6 m walking speed test. However, no significant effect was found for cognitive responses.

In another research conducted in Brazil (36), patients suffering from AD underwent a varied exercise program for 6 months that included various exercises, circuits, sport

dance sequences, recreational activities, stretching activities, weight training and relaxation. The results clearly indicated that cognitive functions (measured using the MMSE) were preserved during the interventional period, while the control group, whose members maintained their routine activities (no exercise), experienced a significant decline in MMSE score.

As for studies which particularly examined the effect of strength and strength training has on AD patients, in a cross-sectional study, Petrella *et al*. (37) evaluated the relationship between quadriceps muscle strength and cognitive impairment (CI) among frail elderly patients and physically independent patients. In this way, an inverse correlation was found between muscle power and CI in the physically independent individuals - that is, as results from the power tests decreased for the quadriceps muscle, signs of CI increased.

Similarly, Scherder *et al*. (38) found that in older women quadriceps muscle strength was associated with an improvement in completing function activities, such as attention and working memory.

Lastly, the increase in muscle strength was associated with a lower rate of decline in global cognitive function. However, despite this association between muscular fitness and cognitive function, relatively few studies have examined independently the effect of strength training on cognitive responses. Cassilhas *et al*. (39) studied the effect of 6 months of strength training on cognitive function in the elderly. In this study the intervention compared different intensities of strength training and the sample was distributed between moderate intensity (50% one-maximum repetition), high intensity (80% one-maximum repetition), and a control untrained group. In terms of muscle strength, both experimental groups performed better than the control group, but no differences were noted between them. Also, in both experimental groups (moderate and high intensity), positive changes were noted in cognitive function.

Furthermore, Liu-Ambrose *et al*. (40) investigated the effect of different frequencies of strength training (once a week compared to twice a week) or twice-weekly balance training on changes in cognitive function in older women. Their results demonstrated that12 months of once- or twice-weekly strength training significantly improved Stroop test performance in cognitively healthy women aged 65-75 years compared to the other two intervention groups.

Likewise, Nagamatsu *et al*. (41) demonstrated that 6 months of twice-weekly strength training improved selective attention/conflict resolution, associative memory and regional patterns of functional brain plasticity, as compared with twice-weekly balance exercises, providing novel evidence that strength training can benefit multiple domains in those at risk for dementia.

Furthermore, another study conducted on senior women with subjective memory complaints, six months of twice-weekly resistance training improved selective attention/conflict resolution, associative memory and regional patterns of functional brain plasticity, when compared with twice-weekly balance and tone exercises. In contrast, six months of twice-weekly aerobic training improved only physical function (41).

Also, some studies analyzed the impact that strength training has on specific age groups of patients with AD. As already

mentioned, Liu-Ambrose *et al*. demonstrated that 12 months of twice-weekly resistance training significantly improved Stroop Test performance in cognitively-healthy women aged 65-75 years old (40), while the same research group found later an improvement after only six months in women aged 70-80 years old with probable mild cognitive impairment. Thus, the benefits of resistance training on selective attention/conflict resolution may be more potent among those at greater risk for dementia.

In addition, loss of muscle strength is common and associated with a variety of adverse health outcomes in old age, but few studies have examined the association of muscle strength with the risk of AD or MCI.

Thus, Boyle *et al*. performed an analysis of 3.6 years on 138 persons who developed AD. The results showed in a proportional hazards model adjusted for age, sex, and education, each 1 unit increase in muscle strength at baseline was associated with about a 43% decrease in the risk of AD. The association of muscle strength with AD persisted even after adjustment for several covariates, including body mass index, physical activity, pulmonary function, vascular risk factors, vascular diseases and apolipoprotein E4 status. Furthermore, in a mixed-effects model adjusted for age, sex, education and baseline level of global cognition, increased muscle strength was associated with a slower rate of decline in global cognitive function. Finally, muscle strength was associated with a decreased risk of MCI, the precursor to AD (42).

Considering all these aspects, we can state that future research might assess the cost-effectiveness of the exercise interventions for the reduction of CI in AD, considering that for example in 2000 the cost of AD and CI treatment in the USA was estimated to be 100 billion US$. This could also have an increased relevance considering that there are a lot of issues that can be tackled by this alternative approach, including for example the self-neglect (43) aspects in these disorders discussed here, as well as various other aspects such as the overmedication (44) and other psychological, social or awareness issues on this matter (45, 46).

Still, although there is accumulating evidence for the effectiveness of exercise in combating cognitive decline, it is believed that there is still a gap in the literature on the indirect and economic costs of physical exercise interventions for CI and AD (47).

CONCLUSIONS

Thus, the current knowledge supports physical activity as an important preventive factor against the onset of Alzheimer's disease and that physical exercising could be crucial for the maintenance or for slowing down the decline of optimal functional ability levels in these patients. However, there is currently insufficient information to enable a precise definition of the best exercise regimen for patients with AD. Also, aerobic exercise is a necessary part of the treatment for AD, but aerobic exercise alone is probably not the best activity. Strength/power training, balance/coordination, and other types of physical exercises also contribute to reconditioning, maintaining, and improving the cognitive and motor functions of AD subjects. Therefore, it is advisable to combine aerobic exercises with other activities that are beneficial for the neuromuscular system (e. g., strength/power training and stretching), balance function, and the performance of motor coordination.

NEWS

THE FUTURE IS NEAR: PARKINSON'S DISEASE – DIAGNOSIS

Parkinson's disease is a neurodegenerative disorder often confused with other atypical parkinsonian syndromes because of its difficult differential diagnosis. Due to recent technological progress in magnetic resonance imaging, the diagnosis of Parkinson's disease has considerably improved. A group of scientists from Innsbruck Medical University decided to write a review that focuses on the value of MRI techniques, including advanced sequences at high and ultra-high-field MRI. Imaging markers for neurodegeneration refers to loss of tissue volume, signal changes and increased iron deposition. Both structural and quantitative imaging techniques are analyzed, the latter including modern techniques such as diffusion imaging, magnetization transfer imaging, iron-sensitive sequences and sequences based on T1, functional imaging techniques including proton magnetic resonance spectroscopy, arterial spin labeling and rs-fMRI. In conclusion, advanced MRI techniques are nowadays used to make a correct differential diagnosis as well as for the early detection of Parkinson's disease. *(*Heim B, Krismer F, De Marzi R, Seppi K. Magnetic resonance imaging for the diagnosis of Parkinson's disease. *J Neural Transm* 2017; 124: 915-964)

3. Disciplina de Psihiatrie

STUDY ON SEVERAL FACTORS INFLUENCING ANTIOXIDANT ENZYME DEFENSE IN OVERWEIGHT PATIENTS (Abstract): The notion of "oxidative stress" was introduced by Sies, in 1985, and designates all the oxidative damages caused by the free radicals of oxygen. Oxidative stress represents the imbalance of pro-oxidant and antioxidant ratio, in favor of the former, following the excessive action of the "aggressor" and/or the decrease of the "defender's" capacity to oppose. **Material and method**: In the current study we had 82 overweight patients (42 patients less than 65 years old and 40 patients over 65). The criteria for inclusion was weight over 80 Kg and BMI > 30. Patients were monitored and assessed every three, six, nine months and each year. **Results**: Obesity together with dyslipidemia, smoking, diabetes and high blood pressure intensifies oxidative stress. The improvement of these factors determines the growth of antioxidant enzyme level (SOD and GPX) and the reduction of malondialdehyde level. **Key words**: OXIDATIVE STRESS, OBESITY, ANTIOXIDANT ENZYME

Stresul oxidativ (SO) reprezintă o importantă verigă fiziopatologică pro-ateroscleroticăîn HTA, dar cu impact semnificativ crescut la persoanele vârstnice.

Stresul oxidativ pare a juca un rol vital în debutul şi progresia arterosclerozei. Efectele dăunătoare cauzate de speciile reactive de oxigen apar ca urmare a unui dezechilibru între formarea şi inactivarea radicalilor liberi de oxigen.

Inactivarea şi eliminarea speciilor reactive de oxigen (SRO) depinde de reacţii care implică sisteme de apărare antioxidante, dintre care cele mai importante sunt reprezentate de superoxid dismutază (SOD) şi glutation peroxidază (GPX) (1,2).

Radicalii liberi pot avea şi unele efecte benefice asupra organismului – de exemplu colaborează cu sistemul imunitar pentru a distruge bacteriile şi alţi invadatori ai organismului sau reglează tonusul muşchilor netezi vasculari contribuind astfel la controlul circulaţiei. Dar acumularea unei cantităţi crescute de radicali liberi ar fi pusă în legătură directă cu fenomenele de îmbătrânire şi de instalare a unor boli cronice (3).

Superoxidismutaza (SOD) reprezintă prima linie de apărare a organismului în faţa stresului oxidativ şi principalul „scavenger" al superoxidului în toate celulele cu metabolism predominant aerob.

Enzima catalizează dismutarea a doi radicali superoxid care se unesc şi formează peroxidul de hidrogen controlând astfel nivelul anionilor superoxid şi împiedicând iniţierea reacţiilor de formare a nocivilor radicali hidroxil şi peroxinitrit.

Pot exista variaţii interindividuale în ceea ce priveşte capacitatea de apărare antioxidantă, ceea ce afectează sensibilitatea indi-

TABELUL I
Corelaţii dintre stresul oxidativ, obezitate, fumat

		OBEZITATE	FUMAT
GPX iniţial	Pearson Correlation	-,689	-,401
	Sig. (2-tailed)	,000	,000
	N	82	82

vidual㠠împotriva efectului dăunător al reacţiilor oxidative (4,5).

MATERIAL ŞI METODĂ

În studiu au fost incluşi 82 de pacienţi obezi (42 de pacienţi cu vârste până în 65 de ani şi 40 pacienţi de peste 65 ani).

Criteriile de includere au fost greutatea peste 80 kg şi un indice de masă corporală peste 30.

Pacienţii au fost monitorizaţi şi evaluaţi la trei luni, şase luni, nouă luni şi un an. S-a considerat astfel că o evaluare la intervale fixe de timp reprezintă un factor predictiv şi de urmărire mai important al patologiei cardiovasculare şi/sau dismetabolice în cadrul loturilor studiate.

Pentru studierea existenţei unei relaţii între obezitate şi stresul oxidativ s-a realizat analiza de corelaţie între valorile GPX, SOD şi MDA şi prezenţa sau absenţa obezităţii.

REZULTATE ŞI DISCUŢII

Din tabelul I se poate observa că prezenţa obezităţii se corelează cu un nivel scăzut al enzimelor antioxidante (rGPX=-0,68 ; pGPX =0,00 ; rSOD=-0,112, pSOD=0,003) şi unul crescut al MDA (rMDA=0,22 ; pMDA =0,001).

Pentru studierea existenţei unei relaţii între fumat şi stresul oxidativ s-a realizat analiza de corelaţie între valorile GPX, SOD şi MDA şi prezenţa sau absenţa fumatului.

De asemenea, din tabelul I se poate observa că prezenţa fumatului se corelează cu un nivel scăzut al enzimelor antioxidante (rGPX= -0,401 ; pGPX=0,00 ; rSOD= -0,148, pSOD=0,002) şi unul crescut al MDA (rMDA=0,901 ; pMDA=0,001).

Pentru demonstrarea unei relaţii între dislipidemie şi stresul oxidativ s-a realizat analiza de corelaţie între valorile GPX, SOD şi MDA şi prezenţa sau absenţa dislipidemiei.

Din tabelul II se distinge faptul că prezenţa dislipidemiei se corelează cu un nivel scăzut al enzimelor antioxidante (rGPX= -0,114 ; pGPX=0,00 ; rSOD= -0,487, pSOD =0,00) şi unul crescut al MDA (rMDA= 0,237 ; pMDA=0,00).

Corelaţia dintre diabetul zaharat şi stresul oxidativ s-a remarcat prin efectuarea analizei de corelaţie între valorile GPX, SOD şi MDA şi prezenţa sau absenţa diabetului

TABELUL III
Corelaţii dintre stresul oxidativ şi hipertensiunea arterială

		AHC - HTA
GPX iniţial	Pearson Correlation	-,651
	Sig. (2-tailed)	,001
	N	82
SOD iniţial	Pearson Correlation	-,192
	Sig. (2-tailed)	,003
	N	82
MDA iniţial	Pearson Correlation	,123
	Sig. (2-tailed)	,000
	N	82
HTA	Pearson Correlation	1,000
	Sig. (2-tailed)	
	N	82,000

în antecedentele heredocolaterale.

În cadrul tabelului II este prezentat faptul că prezenţa diabetului se corelează cu un nivel scăzut al enzimelor antioxidante (rGPX = -0,43 ; pGPX=0,003 ; rSOD= -0,168, pSOD=0,000) şi unul crescut al MDA (rMDA=0,99 ; pMDA=0,001)

Realizarea analizei de corelaţie între valorile GPX, SOD şi MDA şi prezenţa sau absenţa hipertensiunii arteriale în antecedentele heredocolaterale, prezentată în tabelul III demonstrează că prezenţa HTA se corelează cu un nivel scăzut al enzimelor antioxidante (rGPX= -0,65 ; pGPX=0,00 ;

rSOD= -0,192, pSOD=0,003) şi unul crescut al MDA (rMDA=0,123 ; pMDA=0,000).

Bolile cardiovasculare se corelează cu intensificarea stresului oxidativ, demonstrate de scăderea nivelului enzimelor antioxidante (SOD şi GPX).

CONCLUZII

Obezitatea alături de fumat, dislipidemie, diabet şi hipertensiune creşte stresul oxidativ. Ameliorarea acestor factori duce la creşterea nivelului enzimelor antioxidante (SOD şi GPX) şi scăderea nivelului malondialdehidei.

Bolile cardiovasculare se corelează cu intensificarea stresului oxidativ, demonstrate de scăderea nivelului enzimelor antioxidante (SOD şi GPX).

Posibilele surse ale stresului oxidativ din diabetul zaharat includ creşterea producţiei de specii de radicali de oxigen, în special din procesele de glicare sau lipoxidare şi scăderea sistemului de apărare anti-oxidare enzimatic sau non- enzimatic.

Ateroscleroza este o stare în care nivelul stresului oxidativ este ridicat, caracterizată prin oxidarea lipidelor şi proteinelor în peretele vascular.

FIVE-YEAR CLINICAL EXPERIENCE WITH MENINGOCOCCAL INFECTIONS IN INFECTIOUS DISEASES HOSPITAL "SF. PARASCHEVA" IAŞI DURING 2014-2018 (Abstract**): Aim:** To evaluate the epidemiological, clinical-biological and therapeutic data and to assess the influence of standard pretreatment prognosis score on the evolution on meningococcal infection. **Material and methods:** Retrospective analysis of the hospital-based medical records of patients with acute meningococcal infections admitted to the Iaşi Clinic of Infectious Diseases between 2014 and 2018. Selection of patients with classic clinical symptoms of meningitis was based on Gram staining, culture and latex agglutination. The risk factors for complications or death were assessed. **Results:** A total of 370 meningitis patients hospitalized between 2014 and 2018 were reviewed. Meningococcal infections were recorded in 8.05% cases of bacterial meningitis. CSF cultures were positive for only 60% of the study patients. Co-agglutination was clinically useful for confirming the diagnosis in 38% cases. Mortality rate was 14.3% and was related to meningococcemia. Platelet count was the most important predictor in fatal cases. The results showed a poor correlation between length of hospital stay and standard pretreatment prognostic score (r=0.201). **Conclusions:** Meningococcal infection remains a significant health problem because of its serious complications and high mortality rate. The results of this study highlight the importance of implementing the meningococcal immunization programs in our country. **Keywords**: MENINGOCOCCEMIA, MENINGITIS, MENB VACCINE.

Invasive meningococcal disease (IMD) remains a life-threatening disease and an important public health problem worldwide. Of the at least 12 identified serogroups of *Neisseria meningitidis*, six (namely A, B, C, Y and W) are responsible for the majority of cases, and serogroups B and C are the most frequent in Europe (1). *Neisseria meningitides* causes two serious diseases: meningococcal meningitis and fulminant meningococcemia which often occur together.

IMD was recorded as sporadic cases, focal outbreaks, or large epidemics (2). The incidence of IMD varies by geographic region, but also by socio-economic status,

with the highest records in African countries, 10 to 1,000 cases per 100,000 population (3). IMD is rare in Europe. In 2012, 0.68 cases per 100,000 population were reported. According to the most recent report of the European Center for Disease Prevention and Control a total of 3,121 cases of infectious meningococcal diseases were reported (with a notification rate of 0.61 confirmed cases/100.000 population) (4). Serogroups C, B, W and Y are responsible for IMD in Europe. Currently, serogroup B is the most common cause of outbreak associated disease after the significantly decrease in incidence of serogroup C-related meningococcal disease after the introduction of the specific vaccine (5). In 2015, almost 55% cases of IMD were associated with serogroup type B (4). The infants less than 1 year of age are at the highest risk of infection, followed by the 15 to 24-year age group. Patients with complement system deficiencies are also at increased risk for infection (mainly meningococcal meningitis) (6).

Even the event rate (like complications or mortality) is lower in case of meningococcal meningitis compared to other types of meningitis, the overall case fatality rate for IMD approximating 10% in developing countries. In addition, the neurological complications are significant in case of IMDs (4).

In this context, the aim of the present paper was to evaluate the epidemiological, clinical and biological features and therapeutic outcomes of IMDs based on clinical practice in the Iași Clinic of Infectious Diseases during a five-year interval.

MATERIAL AND METHODS

Study patients This was a retrospective analysis of hospital-based medical records of patients with infectious meningococcal diseases (meningococcal meningitis and/or meningococcemia) admitted to the Iași Clinic of Infectious Diseases between 2014 and 2018. The inclusion criteria were based on: clinical signs (e.g. fever, headache, neck stiffness, petechiae or purpura), blood tests results, at least one cerebrospinal fluid (CSF) test result: Gram stain, culture or latex agglutination. Patients with tuberculosis meningitis, nosocomial meningitis, other confirmed bacterial meningitis or meningoencephalitis were excluded.

Data collection. The following data were collected during the study: demographic data, onset of symptoms, physical examination on admission, blood tests results, CSF examination (appearance, cytology, Gram stain, culture, latex agglutination), computer tomography (CT) scan (if available), medication administered (name and duration of treatment) and outcome.

Prognostic score at admission was calculated using the updated Stiehm and Damrosch criteria (1966), namely: presence of petechiae for less than 12 hours prior to admission; cardiogenic shock/hypotension (systolic blood pressure 70 mmHg or below); absence of meningitis (less than 20 white blood cells/mm^3 in CSF); blood leukocyte count normal or low (less than10,000 white blood cells /mm^3); normal or low erythrocyte sedimentation rate (less than 10 mm/hour); thrombocytopenia, hyperpyrexia (7). In addition, fatality rate was calculated.

Statistical analysis Results were analyzed with descriptive statistics. The relationship between prognostic score at admission and disease course was evaluated using Pearson correlation test. Statistical analysis was performed using XLSTAT

version 2018 software.

Ethical approval This retrospective study was approved by the Ethics Committee of the Iasi Clinic of Infectious Diseases.

RESULTS

Patient characteristics Between 2014 and 2018, 370 cases of meningitis were admitted to our clinic. Meningococcal infections were recorded in only 8.57% cases of bacterial meningitis. The mean age of patients was 8.5 years (range 3 months – 69 years), but most patients were aged 1-5 years (fig. 1).

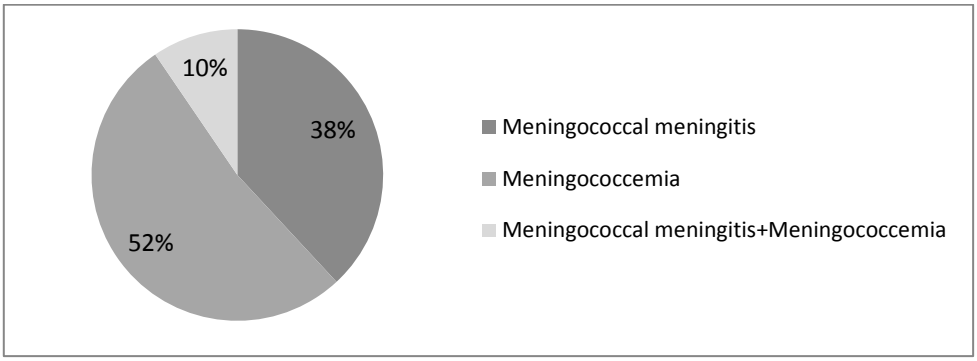

Fig. 1. Age distribution of study patients

The male: female ratio was almost 1:1. Meningococcal meningitis and meningococcemia were diagnosed together in most of the cases (fig. 2).

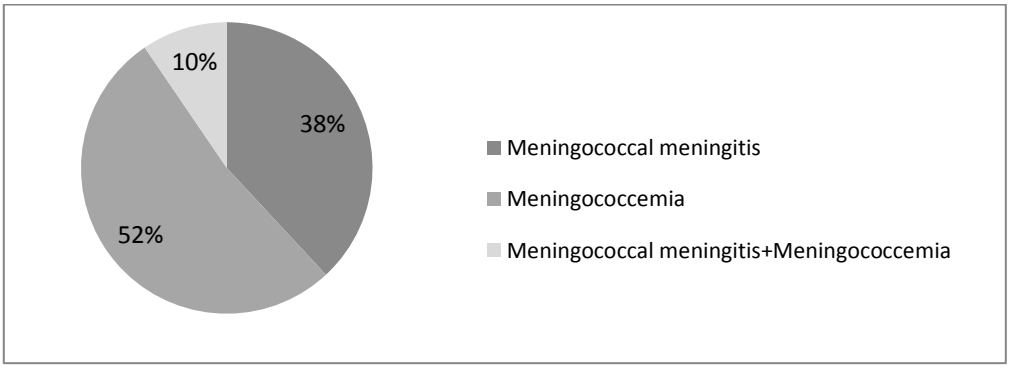

Fig2. Distribution of patients according to their diagnosis

Neisseria meningitides serogroup C was found only in two patients and serogroup B was identified in the remaining cases.

Clinical results. The clinical triad fever, neck stiffness, petechiae was identified in all pediatric patients. Symptom onset was less than 12 hours in81% cases. Level of consciousness was one of the most important criteria of severity considered. Changes in mental status from somnolence to loss of consciousness and coma were recorded in all cases. In the most severe cases, signs of coma (Glasgow 3), encephalopathy and convulsions were noted.

Biological results Mean leukocyte count was 18,358/mm^3 with neutrophils (%) between 29.5 and 93.2%. Leukocytosis was found in 80.95% cases.

Mean platelet count was 22,872/mm^3 and the lowest levels (16,000/mm^3) were identified only in patients with meningococcemia.

CSF findings Lumbar puncture and CSF collection were performed in all cases except two cases of meningococcemia where the significantly low level of thrombocytes contraindicated the procedure (tab. I). CSF analysis revealed pleocytosis in 52.4% cases, elevated protein levels in 62% cases and low glucose levels in only8.6% cases.

Overall, Gram stain test was positive in 52% cases. Positive cultures for *N. meningitides* were obtained in 43% cases. Latex agglutination test confirmed the diagnosis in 38% cases (Table II).

Treatment and outcomes. The prognostic factor was calculated for each patient before initiation of therapy. The values ranged between 1 and 4 but were not directly correlated with disease course (fig. 3).

TABLE I

CSF analysis

CSF parameter	Median (range)
Cell count (cells/mm^3)	1,266 (8 – 11,000)
Albumin (g/L)	1.75 (0.17 – 7)
Glucose (mg/dl)	57.0 (6 – 162)

TABLE II

CSF susceptibility tests

Positive susceptibility Tests (% cases)	Gram stain	CSF culture	Latex co-agglutination
Meningococcal meningitis	66.6	66.6	16.6
Meningococcal meningitis + Meningococcemia	63.64	45.4	54.5
Meningococcemia	0	0	25

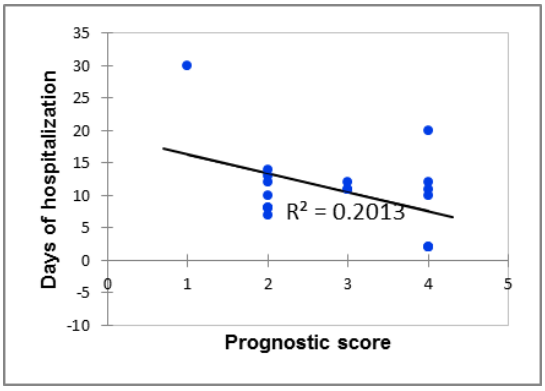

Fig 3. Correlation between days of hospital stay and prognostic score

The fatality rate was 14.3%. Three cases of fulminant meningococcemia had a rapidly progressive course, death occurring within less than 24 hours. Severe thrombocytopenia was the most important predictor of fatal outcome.

The remaining cases responded favorably to treatment with third generation semisynthetic cephalosporin (ceftriaxone), with a mean duration of treatment of 14 days.

DISCUSSION

We conducted a small sample size retrospective study that included 21 patients with meningococcal meningitis, meningococcemia or both. The small number of cases identified in the hospital database was expected since Romania is one of the European Union (EU) countries with a low incidence of IMDs. The notification rate for *N. meningitides* serogroup B recorded by the European Centre for Disease Prevention and Control (ECDC) in 2015 was 0.09 per 100,000 (8).

A previous multicenter study (9) that included our hospital among the participating hospitals reported an incidence of meningococcal diseases of 40 and 16 per 100,000 per year for children < 1year and 1 to 5 years, respectively. In our study, the majority of patients were aged under 5 years (75% cases), of which 33.3% cases were infants < 1-year-old.

Diagnosis was based on medical history, clinical examination, including signs of meningitis, blood tests and CSF analysis. The typical clinical (fever, neck stiffness, petechiae) and laboratory features (CSF analysis) of IMDs were present in all patients. However, the standard criteria to be met for positive diagnosis were very variable, as also noted in other surveillance studies (10).

Neisseria meningitidis was identified based on Gram stain method in less than 70% cases. This result was low compared to other reports, but a high variability of this test was reported in the literature (30 – 89%). A positive latex agglutination test identified the specific bacterial antigen in 50% cases. This result was expected since this method is characterized by a variable sensitivity (22-93%) (11, 12). A PCR analysis, the most sensitive and specific test in the diagnosis of IMDs, since at least one Gram stain, culture and/or latex agglutination tests were positive (13). *N. meningitidis* is some bacteria which rarely develops resistance to penicillin. In a trial performed on 506 *N. meningitides* strains, only 13% cases were identified as intermediate resistant and none of them were resistant to penicillin (14). By contrast, in our study we recorded penicillin resistance in 9% of the cases and intermediate resistance to penicillin in 20%, but the significance of these results could be affected by the small sample size. According to antimicrobial susceptibility tests and current guidelines, Ceftriaxone was selected for IMD treatment. It is well known that early diagnosis and initiation of antibacterial treatment are keys to avoid complications and death in IMDs (2, 15). Procedures like lumbar puncture or CT scan are often responsible for delayed treatment initiation (16). Specific IMD prognostic scores (e.g. Glasgow meningococcal septicemia prognostic score, Stiehm and Damrosch score, Niklasson score) were developed to quantify disease severity. In our study, the Stiehm and Damrosch score was calculated at admission. This factor score could not be accurately correlated with disease course. Of the factors found to be involved in the un favorable progression of IMDs (such as hypotension, tachycardia, low CSF protein level, high CSF/blood glucose, etc.) (16), we have identified thrombocytopenia as a major negative prognostic factor associated with disease-related mortality.

It was reported that almost 500 million people are carriers of *N. meningitidis*. Even though not all of these people develop acute disease, its epidemiological features and life-threatening risk classify the IMDs as a health problem (17).

In this context, prevention becomes one of the most important objectives in the management of IMDs. Chemoprophylaxis (quinolones, rifampin, ceftriaxone) and immunoprophylaxis (mainly meningococcal ACWY oligosaccharide conjugate vaccine) have been demonstrated to be effective in reduction of bacterial carriage of *N. meningitis* and prevention of meningitis-related complications and death (18). More recently, the first meningococcal B vaccine (menB) was authorized in EU for children with age over 2 months and in 2017 was licensed the second menB vaccine for children over 10 years. Also in 2017, ECDC reported the evaluation performed by most of the EU countries regarding the necessity of implementing the immunization program, based on: epidemiology of IMDs, efficacy, safety and immunogenicity of vaccine; cost- effectiveness studies. The European countries have expressed different opinions on this issue. For instance, countries like UK, Ireland, and Italy have already developed and implemented national immunization programs. By contrast, other countries (e.g. France, Belgium) do not recommend vaccination for different reasons. Romania, among other countries (e.g. Denmark, Netherlands, Bulgaria) has not made any decision (19). Romanian public health authorities should evaluate the effectiveness of mass immunoprophylaxis in case of suspected outbreak of meningitis and to define the target population to be vaccinated based on benefit-risk assessment.

CONCLUSIONS

In our retrospective study, typical clinical and laboratory presentations were common, but the positive criteria for IMDs were variable. The fatality rate was low. The prognostic score calculated at admission was not directly correlated with disease course, but low platelet count was one of the most significant predictors of meningococcemia-related mortality.

CLINICAL AND PARACLINICAL FEATURES IN DIABETIC PATIENTS CHOLECYSTECTOMIZED FOR GALLSTONES (Abstract) : Gallstones and diabetes mellitus represent a major economic burden especially when surgical treatment is involved. **Aim** : The purpose of our study is to identify particular laboratory, imaging and pathological aspects that correlate with gallstones in diabetic patients that undergo cholecystectomy. **Material and method** : This retrospective study enrolled 234 subjects diagnosed and treated through cholecystectomy for gallstones during 01.01-31.12.2008 at the 1st Surgical Clinic, Iaşi "St. Spiridon" Hospital. The subjects were divided into 2 groups comprising 62 patients diagnosed with diabetes mellitus and gallstones (group I), respectively 172 patients diagnosed only with gallstones (group II). **Results** : There is a statistically significant difference between the two groups regarding ASA class ($p=0.002$), body mass index, leukocyte count, serum amylase ($p=0.001$) and alanine--aminotransferase levels. Ultrasound examination revealed thickness of the gallbladder wall as an edematous aspect at 29.03% of the diabetic patients vs 13.95% nondiabetic patients and cholesterolotic appearance at 6.45% diabetics vs 2.91% nondiabetics. Pathological examination identified chronic cholecystitis at 88.96% of the diabetic and 70.97% of the nondiabetic patients ; there was no significant difference regarding the gallbladder pathological aspects. **Conclusion** : Diabetes mellitus does not appear to modify substantially the pathological course in patients with gallstones. There is a greater surgical risk for diabetic patients, possibly due to higher body weight and older age in this group and an increased risk for hepatopancreatic lesions. **Key words** : DIABETES MELLITUS, GALLSTONES, CHOLECYSTECTOMY

Litiaza biliară veziculară şi diabetul zaharat (DZ) sunt afecţiuni multifactoriale, caracterizate printr-o incidenţă crescută în populaţia generală şi reprezintă o încărcătură economică majoră pentru sistemul de sănătate, în special atunci când este implicată conduita chirurgicală a colelitiazei - colecistectomia. Asocierea celor două condiţii a fost sugerată de studiile epidemiologice, care au constatat prevalenţa de 2-3 ori mai mare a litiazei biliare la diabetici faţă de populaţia generală, relaţia fiind controversată datorită suprapunerii unor factori de risc pentru ambele boli : vârsta înaintată, obezitatea, dislipidemia, antecedentele familiale (1,2,3). La pacientul diabetic, cei mai importanţi factori litogenici incriminaţi sunt suprasaturarea în colesterol a bilei, hiperinsulinismul şi afectarea motilităţii colecistului, datorată neuropatiei autonome şi răspunsului diminuat al musculaturii netede veziculare la colecistokinină (4,5,6,7). Hiperinsulinemia pare să joace un rol mult mai important faţă de hiperglicemie în geneza calculilor, ceea ce determină o asociere mai puternică între litiaza biliară şi diabetul zaharat de

tip 2 (7). În ceea ce priveşte componenta chirurgicală a tratamentului, pacientul diabetic este, cel puţin teoretic, mai predispus la complicaţii perioperatorii, datorită afecţiunilor coexistente, cardiovasculare şi renale, precum şi riscului septic crescut.

Scopul prezentei lucrări este de a identifica şi de a demonstra câteva aspecte particulare ale tabloului biochimic, imagistic şi morfopatologic al pacienţilor diabetici colecistectomizaţi pentru litiază biliară veziculară, comparativ cu nondiabeticii supuşi aceleiaşi intervenţii curative.

MATERIAL ŞI METODĂ

S-a realizat un studiu de cohortă pe un număr total de 234 de pacienţi internaţi şi colecistectomizaţi în Clinica I Chirurgie a Spitalului "Sf. Spiridon" din Iaşi, în perioada 1.01.2008 – 31.12.2008. Pacienţii au fost împărţiţi în 2 loturi de studiu: lotul I, format din 62 de pacienţi cu diabet zaharat de tip 1, tip 2 sau tip 2 insulinotratat şi lotul II, format din 172 de pacienţi nondiabetici.

Bolnavii au fost incluşi într-unul dintre cele două loturi pe baza următoarelor criterii: diagnostic clinic şi imagistic de litiază biliară veziculară, rezolvată chirurgical prin colecistectomie (laparoscopică, clasică sau convertită), antecedente personale de DZ pentru includerea în lotul I sau absenţa acestui diagnostic (includerea în lotul II), absenţa evidenţelor imagistice sau intraoperatorii de litiază coledociană. Criteriile de excludere din studiu au fost reprezentate de litiaza coledociană, colecistectomie la o spitalizare anterioară, antecedentele personale de hepatită toxică, autoimună sau virală B şi C, bolile hepatice de stocaj, cirozele hepatice şi polipii veziculari.

Parametrii analizaţi au fost preluaţi din foile de observaţie clinică, protocolul operator aferent şi datele prezente în buletinele de examinare imagistică şi morfopatologică a specimenelor recoltate intraoperator. Informaţiile obţinute au fost grupate în date demografice şi clinice, parametri biochimici funcţionali hepatopancreatici (transaminaze, amilaze serice, fosfatază alcalină, bilirubină), număr total de leucocite, date ecografice (grosimea peretelui colecistic, numărul şi dimensiunea calculilor) şi aspecte microscopice ale piesei de rezecţie (veziculă biliară).

Datele au fost analizate şi exprimate în termeni de valori medii, exprimări procentuale şi deviaţie standard. Diferenţele semnificative dintre valorile medii au fost investigate cu ajutorul testelor *t-Student* şi *ANOVA*. Prelucrarea statistică a fost realizată prin intermediul programului *Statistica 8.0*.

REZULTATE

Parametrii demografici şi clinici: vârsta medie a pacienţilor incluşi în studiu a fost de $62,09 \pm 12,5$ ani în cazul pacienţilor diabetici şi de $55,19 \pm 13,08$ ani în cazul pacienţilor nondiabetici. În ambele loturi s-a înregistrat o prevalenţă crescută a pacienţilor de sex feminin, cu un raport dublu în favoarea acestora în cadrul lotului de nondiabetici (4, 2 : 1) faţă de lotul cu DZ (2,1 :

*AST – aspartat-aminotransferaza **ALT – alanin-aminotransferaza

1). În ceea ce priveşte indicele de masă corporală (IMC), valorile medii ale acestuia au fost semnificativ mai mari la pacienţii diabetici, situându-se în intervalul corespunzător supraponderii şi obezităţii (tab. I).

Prin utilizarea clasificării ASA (*American Society of Anesthesiologists*), care evaluează riscul operator ţinând cont de statusul fizic al pacienţilor (8) şi analiza antecedentelor patologice personale, a tabloului clinic, bolnavii au fost incluşi într-una dintre următoarele categorii: clasa I (stare de sănătate bună), clasa II (patologie sistemică uşoară, fără afectare funcţională) şi clasa III (patologie sistemică severă, care limitează activitatea dar nu este incapacitantă); afecţiunile sistemice asociate cel mai frecvent au fost diabetul zaharat (100% în lotul I) şi hipertensiunea arterială (ambele loturi). Analiza comparativă a celor două loturi a relevat că pacienţii diabetici au prezentat un risc operator semnificativ crescut comparativ cu pacienţii non-diabetici (14,52% dintre pacienţii din lotul I au înregistrat scorul III pe scala ASA, spre deosebire de 4,07% dintre pacienţii lotului II).

Parametrii biochimici ai funcţiei hepatopancreatice au înregistrat diferenţe semnificative între cele două loturi studiate pentru valorile alanin-aminotransferazei (ALT) şi amilazemiei ($p=0,001$); markerul **inflamator**, reprezentat de numărul total de leucocite, a fost mai bine reprezentat în lotul diabeticilor, atingând nivelul de semnificaţie statistică ($p=0,032$) (tab. II).

Examenul ecografic a comparat grosimea pereţilor colecistului, dimensiunea şi numărul calculilor. În cazul ambelor loturi s-a evidenţiat îngroşarea marcată a pereţilor veziculei biliare, având ca substrat principal edemul (29,03% vs 13,95%) şi colesteroloza (6,45% *vs.* 2,91%); pereţii veziculei

* VB – vezicula biliară

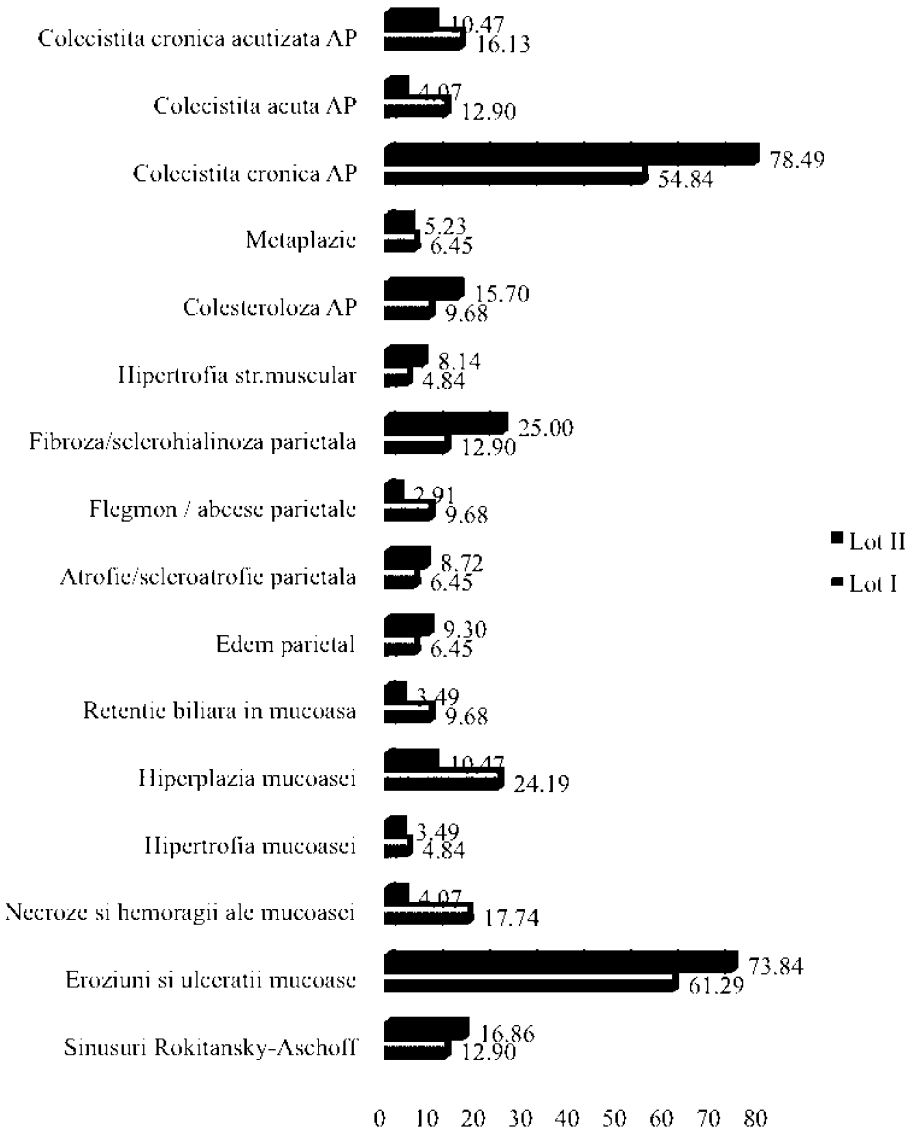

Fig. 2. Aspecte morfopatologice ale veziculei biliare la pacienţii colecistectomizaţi

biliare au avut un aspect normal ecografic la numai 3,23% dintre diabetici şi la 5,81% dintre pacienţii fără DZ (fig.1).

Calculii au avut dimensiuni extrem de variabile, de la microcalculi la dimensiuni relativ mari (20-25 mm); la 69,35% dintre pacienţii diabetici şi la 75% dintre pacienţii celui de-al doilea lot, calculii au fost multipli, fără a se înregistra diferenţe cu relevanţă statistică (tab. III).

Examenul morfopatologic al colecistului a obiectivat modificări la nivelul peretelui şi al mucoasei, majoritatea corespunzând tabloului colecistitei cronice calculoase sau unui puseu acut suprapus pe inflamaţia cronică, aceste aspecte, însumate, fiind mai frecvente la diabetici (88,96% *vs.* 70,97%); la nondiabetici au fost mai frecvente modificările de colecistită acută, abcesele parietale, necrozele şi hemoragiile mucoasei, metaplazia, fără semnificaţie statistică (fig. 2).

DISCUŢII

Analiza demografică a loturilor studiate a evidenţiat necesitatea colecistectomiei începând de la vârste medii şi predominanţa pacienţilor de sex feminin, concordant cu datele cunoscute de epidemiologie a litiazei biliare. În studiul nostru, se remarcă intervenţia chirurgicală survenită la vârste mai înaintate în cazul diabeticilor şi o tendinţă accentuată de scădere a raportului între sexe la diabetici (2,1 : 1) versus nondiabetici, la care sexul feminin predomină net (4,2 : 1); această constatare conduce la ipoteza unei echilibrări a riscului de litiază la diabeticii de ambele sexe, fie prin dezvoltarea unor factori de risc suplimentari pentru litiază, la bărbaţii diabetici, fie prin prezumţia că diabetul zaharat *per se* este un factor de risc mai puternic pentru colelitiază decât sexul feminin. Deloc surprinzător, pacienţii diabetici au avut un IMC semnificativ mai mare decât subiecţii din lotul II de studiu, obezitatea fiind puternic asociată cu colelitiaza, independent de prezenţa diabetului (2,6).

În ceea ce priveşte statusul fizic al pacientului pre-colecistectomie, diabeticii s-au încadrat majoritar în clasa ASA II (85,48%) şi 14,52% s-au încadrat în clasa ASA III, având un risc operator semnificativ crescut ($p=0,002$) faţă de nondiabetici, la care cea mai frecventă condiţie sistemică a fost hipertensiunea arterială, asociată cu un risc moderat. Riscul operator potenţial mai mare se poate explica datorită complicaţiilor sistemice multiple ale diabetului, riscului septic crescut precum şi complicaţiilor dezvoltate perioperator. În studiul nostru, vârsta mai înaintată şi obezitatea prezente la pacienţii diabetici ar putea fi factorii responsabili de diferenţa semnificativă de risc între cele două loturi, într-o măsură mai mare decât simpla evaluare a clasei ASA.

Datele din literatură privind chirurgia tractului biliar relevă un risc aproape similar la diabetici versus nondiabetici, diferenţele notabile fiind reprezentate de o rată mai mare de conversie a colecistectomiei laparoscopice la o intervenţie deschisă, de un risc mai mare de perforaţie a veziculei biliare şi de o incidenţă crescută a colecistitei gangrenoase şi emfizematoase (9,10), date neconfirmate în studiul nostru, posibil şi datorită numărului prea mic de diabetici raportat la cazurile de nondiabetici.

Parametrii biochimici determinaţi la internare au sugerat o injurie hepatocitară, exprimată prin creşterea alanin-aminotransferazei, semnificativ mai mare în lotul I (diabetici) faţă de pacienţii din lotul II. Această citoliză poate fi explicată în contextul inflamaţiei cronice veziculare de vecinătate, cu incidenţă, durată şi severitate mai mare la diabetic, în contextul unui stres oxidativ mai accentuat şi al preexistenţei steatozei hepatice metabolice, condiţie frecventă la diabetic (11,12). În acelaşi context, s-ar putea explica şi afectarea pancreatică mai pronunţată, exprimată prin creşterea amilazemiei, studii recente sugerând o incidenţă mai mare a pancreatitei acute la diabeticii

tip 2, fără a se nominaliza clar factorii cauzali ai acestei creşteri a riscului (13); în absenţa litiazei de coledoc, nu s-au înregistrat modificări semnificative ale parametrilor de colestază (bilirubina totală şi directă, fosfataza alcalină) la pacienţii studiaţi. O relevanţă mai mare decât injuria acută a ficatului ar putea-o avea determinarea seriată a acestor parametri, pentru urmărirea dinamicii lor postoperatorii; un studiu al lui Chang *et al*. a găsit această afectare ca fiind tranzitorie, pericolecistectomie, la pacienţii fără litiază de coledoc (14).

În studiul nostru, parametrii ecografici luaţi în calcul nu s-au dovedit discriminativi între cele două loturi, grosimea pereţilor colecistului, mărimea şi numărul calculilor dovedindu-se similare la cele două grupuri.

Modificările morfopatologice ale veziculei biliare se regăsesc mai ales la nivelul mucoasei, fiind prezente, cel mai frecvent, eroziuni şi ulceraţii, sinusuri Rokitansky-Aschoff, ca expresie a inflamaţiei cronice şi a obstrucţiei fluxului biliar cauzate de calculi, retenţie biliară în mucoasă, colesteroloză, hiperplazia mucoasei. În procente reduse s-au înregistrat aspecte cu grad înalt de severitate: necroze şi hemoragii, abcese sau flegmoane parietale, metaplazia mucoasei, fără ca aceste aspecte să fie mai frecvente la diabetici (15).

Absenţa unor diferenţe semnificative statistic între aspectele morfopatologice la cele două loturi dovedeşte faptul că prezenţa calculilor reprezintă o spină iritativă locală cu agresivitate similară la toţi pacienţii, diferenţele între bolnavi rezultând mai degrabă din complicaţiile sistemice ale diabetului.

Având în vedere aceste date, pare de înţeles de ce colecistectomia profilactică la toţi pacienţii diabetici, mai ales la cei asimptomatici, nu s-a demonstrat a creşte semnificativ calitatea vieţii la diabetic, ba chiar dimpotrivă (9,16).

CONCLUZII

Diabetul zaharat nu modifică fundamental tabloul clinico-paraclinic şi morfopatologic al pacienţilor cu boală litiazică veziculară. Cunoaşterea tabloului paraclinic şi a alterărilor acestuia în contextul asocierii diabetului zaharat cu litiază biliară precum şi evaluarea preoperatorie a complicaţiilor sistemice scade semnificativ riscul perioperator.

La pacienţii studiaţi, singurele elemente biochimice de alarmă au fost creşterea amilazemiei, ca răsunet al afectării pancreatice şi hepatocitoliză mai severă în cazul pacientului diabetic, ambele necesitând determinări în dinamică, pentru evaluarea reversibilităţii modificărilor.

Datele obţinute în studiul actual, coroborate cu informaţiile din literatură, sugerează că diabetul zaharat nu modifică semnificativ evoluţia clinică şi morfopatologică a litiazei biliare dar poate fi indicatorul unui risc crescut de afectare hepatopancreatică perioperator.

MULŢUMIRI

Mulţumim domnului Profesor Dr. Eugen Târcoveanu, pentru amabilitatea de a ne fi permis accesul la arhiva medicală a Clinicii I Chirurgie A, fără de care nu am fi putut realiza această lucrare.

NOUTĂŢI

Dovezi pentru şi împotriva profilaxiei în refluxul vezico-ureteral

Rolul profilaxiei antimicrobiene în refluxul vezico-ureteral (RVU) a devenit o cercetare în ascensiune prin folosirea celor mai bune metode analitice, prin dobândirea de cunostinţe în ceea ce priveşte RVU şi cicatricile renale diagnosticate fară a fi precedate de infecţie urinară (ITU), precum şi datorită celor mai bune metode de diagnosticare a cicatricilor renale. O meta-analiză a celor mai recente 5 studii randomizate cu un total de 809 pacienţi cu RVU diagnosticaţi după ITU relevă un risc relative a recurenţei ITU de 0,82 ş95% interval de confidenţă (CI) 0,62 – 1,08, $p=0,16$ţ cu profilaxie. O meta-analiza a 4 studii cu un total de 662 pacienţi cu ITU cu şi fără RVU evaluaţi pentru cicatrici renale a relevat un risc de 1,04 ş95% CI : 0,84- 1,30 ; $p =$ 0,69ţ cu profilaxie. Totuşi, aceste observaţii, necesita a fi interpretate cu precauţie datorită limitării acestor studii şi a eterogenităţii meta-analizelor, în particular pentru cicatricile renale. Sunt necesare mai multe cercetări pentru a valida rolul profilaxiei în RVU diagnosticat după ITU, mai multe cercetări putând garanta răspunsul la întrebarea privind profilaxia antibacteriană în legatură cu spectrul RVU în diferite circumstanţe clinice (Mattoo TK. Evidence for and against urinary prophylaxis in vesicoureteral reflux. *Ped Nephrol* 2010 ; 25 : 2379-2382).

GUT MICROBIOTA: THE CINDERELLA OF NEUROLOGICAL DISORDERS (Abstract): Gut microbiota (GM) modulates local and systemic immune mediated responses therefore its imbalance might be implicated in the pathogenesis of several human disorders. The pallet is wide including gastrointestinal diseases such as inflammatory bowel disease, irritable bowel syndrome, metabolic diseases such as metabolic syndrome, types 1 and 2 diabetes, allergic disorders and certain tumors. Regarding neurological disorders, dysbiosis is implicated in the pathogenesis of neurodegenerative conditions like Alzheimer's disease, Parkinson disease and amyotrophic lateral sclerosis. New data associate GM alterations with ischemic stroke and epilepsy. Also, a possible link between dysbiosis and myasthenia gravis is discussed. The aim was to synthetize the interaction between GM and the autoimmune system and the possible implications of this interaction in the pathogenesis of several neurological diseases, both autoimmune and non-autoimmune. These cause-effect relations open opportunities regarding potential new treatment measures. **Keywords**: GUT MICROBIOTA DYSBIOSIS, PATHOGENESIS, NEUROLOGICAL DISORDERS, MYASTHENIA GRAVIS, ISCHEMIC STROKE.

In a present time when several exogenous culprits such as antibiotics, preservatives, genetically modified food bombard the human organism through the gastro intestinal tract, gut microbiota (GM) becomes the center of attention as it modulates local and also systemic immune mediated responses. It is known that microbial colonization of the gut begins during the period of birth. The gut microbiota is distinctive of each individual, being influenced severely by numerous factors such as lifestyle, diet, environmental hygiene and metabolism, immune system of the host (1).

In the last two decades, medical publications focused on the alterations in GM, generally called dysbiosis, not only in terms of causes but also in terms of local and systemic repercussions. Many studies suggest that dysbiosis is implicated in the pathogenesis of gastrointestinal diseases such as inflammatory bowel disease, irritable bowel syndrome and *Clostridium difficile* infection (2). This is an important finding due to the fact that these diseases are frequent in the modern era. For exam-

ple, it is widely known that in the last two decades *Clostridium difficile* infection has become a prominent pathology especially among elderly hospitalized patients receiving antibiotics, with an increase in incidence and symptom severity (3, 4, 5).

GM and its alterations seem to play an important role in various diseases outside the gastrointestinal tract. Intestinal microbiota alterations appear to contribute to metabolic diseases such as metabolic syndrome, types 1 and 2 diabetes (6, 7), to allergic disorders and atopy (8) and to tumors both colorectal and extracolonic (9, 10). Regarding neurological disorders, several studies implicate dysbiosis in the pathogenesis of neurodegenerative conditions like Alzheimer's disease, Parkinson disease and amyotrophic lateral sclerosis (11).

Taking into consideration GM`s central immune functions in the gastrointestinal tract it is deducible that these functions can influence the immune system outside the gut. Actually, an increasing number of publications conclude that GM can be involved in the pathogenesis of immune-mediated, extraintestinal diseases such as thrombotic thrombocytopenic purpura and Hashimoto thyroiditis (12). Multiple sclerosis is a relevant example given the fact that both animal and clinical studies have shown its association with the intestinal microbiota (13). Following the same deductive pattern, dysbiosis may be involved in various types of autoimmune encephalitis including the one with N-methyl-D-aspartate receptor antibodies. According to Boangher, these particular antibodies can produce an individual type of autoimmune encephalitis or can be associated with *Herpes Virus* encephalitis (14).

Given the fact that Myasthenia Gravis is an autoimmune disorder caused by autoantibodies produced by autoreactive B lymphocytes and GM seems to influences immune mediated responses, one can extrapolate and assume that GM can be a key etiological factor in this intense studied yet incomplete understood disease of the neuromuscular junction.

The aim of this present article is to synthetize the interaction between GM and the autoimmune system and the possible implications of this interaction in the pathogeny of several neurological diseases, both autoimmune and non-autoimmune.

Gut microbiota –
an organ within an organ

The number of microbial entities in the GM being close to 10^{14} is almost ten times higher than the number of human cells (15). Also, its microbiome outnumbers by one hundred-fold the genes in the human genome (16). This is the picture present in the gastrointestinal tract of an adult and it is the result of diversification and multiplication that start at birth.

Information regarding GM`s composition have been emerging thanks to newer and more advanced molecular techniques. GM is practically an immense ecosystem comprised of over 1000 species of mainly anaerobic bacteria associated also with viruses, protozoa, archaea and fungi (17, 18). From the four phyla that dominate human intestinal microbiota, *Bacteroidetes*, *Actinobacteria*, and *Firmicutes* largely define GM (19).

The composition of the GM varies longitudinally and also transversely. Bacteria density increases downward the gastrointestinal tract with a peak in the colon. Transversely, certain species involved

especially in immune interaction adheres to the mucosal surface while others specialized in metabolic interactions with food are present in the lumen of the gastrointestinal tract (20, 21). Overall, GM composition varies from one individual to another.

Despite individual variations, GM is at an equilibrium which brings benefits to its host. These benefits regard metabolic, protective and trophic functions. GM influences the metabolism of not only cholesterol, polysaccharides and amino acids but also of certain medication, modulating their bioavailability (22, 23). For instance, GM contributes to fermentation of non-digestible polysaccharides into short-chain fatty acids which in turn increase in satiety (24). Also, GM produces certain vitamins as K and from the B group (25).

Pathways of interaction between gut microbiota and the central nervous system

It is well known that the gastrointestinal tract has a well-developed vegetative nervous system named the enteric nervous system which indirectly influences GM by coordinating gut motility and homeostasis (20). On the other hand, GM influences the enteric nervous system by producing many biologically active substances, including neuromodulators and neurotransmitters (26). The enteric nervous system is connected to the central nervous system via the vagus nerve. Therefore, vagus nerve can become a convenient pathway through which GM interacts with the central nervous system.

GM influences the enteric nervous system in several ways among which production of catecholamines, histamine and tryptophan is well known (25). An experimental study performed on mice concluded that normal GM influences cerebral metabolites through the microbiota-gut-brain axis and therefore it can contribute to normal brain development and to superior cortical functions such as memory and learning (27).

Another means is genetical interferences suggested by the fact that bacterial RNA, DNA, and proteins are detected in the human brain (28, 29). Also, short-chain fatty acids can produce epigenetic changes in the central nervous system by translocating in the brain and inhibiting deacetylases (25).

Overall, GM appears to influence nociceptive responses, depression, stress responsiveness, anxiety and social interaction (25). As proof of this theory, there are many publications which suggest that GM dysbiosis can be a cause of neuropsychiatric disorders such as schizophrenia, depression and autism and therefore propose as adjuvant treatment therapies which target the GM (16, 18).

Also, influence of GM on the central nervous system can partially explain Braak's theory in the development of Parkinson's disease. According to this theory, Parkinson disease neuropathology may occur first in the peripheral autonomic pathways and extend to the central autonomic pathways (30).

The influence of gut microbiota on the immune system

One of the modern definitions of human evolution is adapting changes in the human genome. The human genome is constantly interacting with the genome of commensal microorganisms, through epigenetic mechanisms. From the point of view of this "old friend hypothesis", human evolution depends on commensal flora, including GM (31).

In the last decades is has become a general belief that GM can influence the immune system of the host through its interactions with human intestinal cells and the diffuse gut associated lymphoid tissue. In physiological conditions, in the absence of a "leaky gut", GM interacts with human intestinal cells and plasma cells through Toll like receptors (32). Evidence of this immune modulation can be found in the variable IgA repertoire secreted by the intestinal plasma cells. Studies have shown that each individual harbors a private polyclonal and highly diverse IgA repertoire (33). Given the fact that intestinal IgA interacts with microbiota through several specific epitopes and regulates GM homeostasis, the IgA repertoire of a host can be considered a mirror of the actual GM composition (34).

The link between GM and the human immune system is also evident in the fact that some enteral commensal bacteria can influence some types of T lymphocytes. For example, certain species of *Clostridium* and *Bacteroides* can induce production of anti-inflammatory interleukin-10 and activation of regulatory T cells by the Toll-like-receptor pathway activation (35). In this manner, *Bacteroides fragilis*, a major GM bacterium can prevent inflammatory bowel disease. Also, *Firmicutes* can induce regulatory T cells (36). Colonic regulatory T cells can be induced also by short-chain fatty acids which are a product of GM fermentation (20). Also, GM are potent activators of innate lymphoid cells (25).

Gut microbiota and non-autoimmune neurological disorders

Several studies point that dysbiosis is a potential culprit in several neurological disorders. In Parkinson disease, although the mechanism is still unknown, it is proven that patients show a reduced population of *Prevotellaceae* in their fecal matter compared with normal patients. The overpopulation of other families of gut bacteria such as Enterobacteriaceae has been discovered in patients with postural and gait difficulty (36). Also, hypokinesia can be significantly diminished by eradicating *Helicobacter pylori* infection in parkinsonian patients, according to a randomized controlled trial (37).

In the past decade several reports suggest a link between GM composition and stroke outcome (38). The cause-effect relation seems to be mediated through two pathways. On one hand, GM modulates microglial maturation, activation and neuroinflammation through microbiota-derived short chain fatty acids (39). On the other hand, a recent theory points microbiota-dependently activated T-cells as an important pathogenic factor as these cells interact with other immunocompetent cells of the brain after an extensive ischemic lesion (38). A novel idea is a bidirectional relationship between brain and GM-immune axis. According to this, middle cerebral artery occlusions induce a specific change in the composition of GM with a decrease in diversity and an increase in Bacteroidetes phylum. In turn, gut dysbiosis increases brain lesion volume through immune-mediated mechanisms (40). The specific mechanism through which an ischemic brain lesion induces GM alterations is not completely elucidated. However, it has been proven that post ischemic gut dysbiosis are associated with reduced gastrointestinal motility and paralytic ileus, two features of autonomic disfunction (40,

41). This theory is consistent with the well-known fact that large brain ischemic lesions can induce autonomic disfunctions such as different hart rate responses depending on the side of the lesion: right hemisphere infarcts have an enhanced sympathetic control on the heart rate while left hemispheric ones have a dominant parasympathetic control (42, 43).

Epilepsy, one of the most frequent and stigmatizing neurological disorders has recently been linked to autoimmune dysregulations (44, 45). Due to the fact that GM significantly influences responses of the human immune system, both innate and adaptive it is a logical deduction that dysbiosis might be involved in the pathogenesis of idiopathic seizure disorders. According to some experts, a particular high count of *segmented filamentous bacteria* in the GM causes systemic proliferation of T helper 17 lymphocytes which in turn increases the level of interleukin 17-A in the brain. Apparently, high concentration of this cytokine in the cerebral spinal fluid or peripheral blood is correlated with increased seizure frequency and severity (46). Due to the fact that current antiepileptic drugs are quite limited in number and have numerous side effects, one can easily deduce the importance of new therapeutic alternatives, including recolonizing GM (47, 48).

Does gut microbiota contribute to development of neurological autoimmune disorders?

The complex link between GM and human immune system is incompletely understood. So is the etiology of many autoimmune disorders. However, there is evidence of the involvement of GM dysbiosis in the pathogeny of systemic autoimmune disorders such as thrombotic thrombocytopenic purpura, arthritis, systemic lupus erythematosus, Sjogren's syndrome and Hashimoto thyroiditis (12, 49).

The present tendency is to extrapolate the role of GM dysbiosis in the pathogenesis of neurological autoimmune disorders like multiple sclerosis. From an immunopathogenic point of view, multiple sclerosis is considered to be mediated by T lymphocytes and dependent on B lymphocytes: autoreactive T helper cells that have escaped thymic selection infiltrate the central nervous system where they produce inflammatory reactions and activate B lymphocytes (50). These cells along with autoreactive T cytotoxic cells appear to be responsible of the characteristic lesions in the central nervous system. In addition, pro-inflammatory mediators produced by astrocytes and microglia sustain continuous CNS inflammation which promotes gradual neurodegeneration (25). Given the fact that GM influences blood–brain barrier integrity and microglia maturation which are key factors in multiple sclerosis, it is only logically to consider that GM can be involved in this autoimmune neurological disease (51, 52).

Another well-known autoimmune neurological disorder is myasthenia gravis which is mediated by B lymphocyte and dependent on T lymphocyte (53). Myasthenia gravis is an extremely heterogenic disorder which can be classified using both clinical and serological criteria. Myasthenia gravis with antibodies against acetylcholine receptor is the most frequent given the fact that these antibodies can be detected in 85% of patients with generalized clinical form and in 40% of patients with the ocular form (54). This serological subtype of the

disease is caused by synthesis of autoreactive T helper cells within a thymus that lacks normal negative selection. This abnormal T lymphocytes cross- react with acetylcholine receptors situated on the postsynaptic component of the neuromuscular junction. Also there seems to be an alteration in the functionality of T suppressor lymphocytes which will fail to eliminate the autoreactive T effector cells (55).

Although its pathogenesis is well known, the etiology of myasthenia gravis remains partially obscure. Overall it is a multifactorial disease in which various exogenous factors bombard a human organism genetically predisposed to autoimmunity. The genetic predisposition is suggested by the fact myasthenia occurs in 35% of monozygotic twins whereas in heterozygous twins occurs only in 4-5% (22). Also, associations between certain myasthenic subtypes and different Human Leukocyte Antigens complex alleles, with significant differences between Caucasians and Asians indicates genetic implications (56).

Even though there is important evidence of genetic involvement, genetic mechanisms alone do not explain the complexity of myasthenia gravis. Taking into consideration on one side its immunopathogenesis and on the other side, the influence of GM on several T cell types and innate lymphoid cells, one can deduce that there might be a link between GM and myasthenia gravis.

Fecal microbiota transplantation and its role in neurological disorders

Some recent studies describe an important role in restoration of gut microbiota after fecal microbiota transplantation (FMT) and an improvement in some neurological and psychiatric disorders (57). The evidence is based on the modulation process of the gut-brain axis (58).

Recent report in literature relate to FMT as an important role in a widely neurologic and psychiatric disorders such as Parkinson's disease, fatigue, multiple sclerosis and autism (59).

FMT was used in patients with dysbiosis and Clostridium difficile refractory colitis, the technique consists in infusion of feces from a healthy donor in patients gastrointestinal tract (60). Now FMT is used for treatment in multiple sclerosis and autism.

Taking all into consideration, despite the fact that GM has been intensively studied throughout the years there still remains unknown information regarding its influence upon other organs outside the gastrointestinal tract. As knew information regarding its functions emerge, knew pathogenic hypothesis are tested. We are witnessing a tendency to involve GM and its dysbiosis in many autoimmune diseases including neurological ones as multiple sclerosis. Regarding myasthenia gravis and GM there is much uncharted territory, but immunomodulation seems to be the key.

DIGITAL BREAST TOMOSYNTHESIS: A THREE-DIMENSIONAL PICTURE OF THE BREAST

Digital breast tomosynthesis (DBT) creates a 3-dimensional picture of the breast using X-rays.. Digital tomosynthesis of the breast is different from a standard mammogram in the same way a CT scan of the chest is different from a standard chest X-ray. Mammography usually takes two views of each breast: cranio-caudal (CC) and oblique (MLO) view. Classic mammography records the pictures on film and digital mammography records the pictures in the computer. Mammograms are very good, but they have a significant limitation: the breast tissue and the pathology are overlapped, so breast cancer can be hidden in the overlapping breast tissue. Digital tomosynthesis overcomes this issue by taking multiple slices of each breast in CC and MLO projections; in DBT the X-ray tube makes an arc, during which a series of images is acquired; the acquisition time is 10-20 sec, slice thickness is 1mm and the images can be displayed in different ways (single slice, slab, cine loop. There is a great variability in the number of the acquired slices (between 13 and 25) and the acquisition angle (between 15 ° and 50 °).Tomosynthesis does not provide direct projection images, but reconstructed images of the individual layers through several available algorithms, more or less efficient, each aimed to remove from reconstructed slice the upper and lower layers. Because is relatively new and its availability is low, this method of examination is not yet used for breast cancer screening , but researchers believe that this new breast imaging technique will make breast cancers easier to see in dense breasts.

CARDIOVASCULAR RISK OF HALOPERIDOL VS. ATYPICAL ANTI-PSYCHOTIC DRUGS IN SCHIZOPHRENIA TREATMENT (Abstract): The present study examined the safety of the atypical antipsychotic drugs sertindol, olanzapine and quetiapine used in the treatment of schizophrenia. Haloperidol, a typical antipsychotic drug, was used for comparison. These data may account for the different therapeutic effects and side-effect profiles (cardiovascular risk) of typical and atypical antipsychotic drugs in schizophrenia. **Key words**: SERTINDOL, OLANZAPINE, QUETIAPINE, QTC

Medicaţia antipsihotică a reprezentat mult timp principalul remediu terapeutic în schizofrenie, odată cu introducerea clorpromazinei şi descoperirea ulterioară a diferitelor substanţe antipsihotice (1). În prezent există un număr impresionant de antipsihotice convenţionale al căror mecanism de acţiune constă în blocarea postsinaptică a receptorilor dopaminici D2, blocarea în diferite grade a receptorilor noradrenergici, colinergici şi histaminici (2). Prin această acţiune se realizează efectele terapeutice în faza acută şi în faza cronică, dar şi o serie de efecte secundare, care limitează eficienţa terapeutică. Noua generaţie de antipsihotice a fost completată prin lansarea olanzapinei, quetipinei, risperidonei, sertindole, zotipine (3,4). Aceste noi antipsihotice acţionează prin blocarea receptorilor D2 şi a receptorilor serotoninici de tip 2A la nivel frontal şi în sistemul striat, fapt care conduce la scăderea efectelor secundare extrapiramidale.

OBIECTIVE

Obiectivul acestui studiu este de a compara profilul de siguranţă al haloperidolului cu olanzapina, sertindolul şi quetiapina, în ceea ce priveşte efectul aritmogen al neurolepticelor prin creşterea intervalului QTc (5).

MATERIAL ŞI METODĂ

Studiul a constat în înrolarea, evaluarea, urmărirea clinico-terapeutică a 60 de pacienţi internaţi în cadrul Spitalului Clinic de Psihiatrie "Socola" între anii 2008-2009.

Pacienţii au fost împărţiţi în 4 subloturi egale în funcţie de medicaţia primită:

- LOT 1 - Haloperidol;
- LOT 2 - Olanzapină;
- LOT 3 - Sertindol;
- LOT 4 - Quetiapină

Criteriile de includere pentru acest studiu au fost:

- bărbaţi sau femei cu vârsta cuprinsă între 18 şi 65 de ani;
- diagnosticaţi cu schizofrenie (orice subtip) conform ICD-10 de cel puţin 1 an;
- să aibă un scor PANSS >70;
- CGI-S $=4$;
- traseu ECG (12 derivaţii) cu aspect mor-

fologic normal ;
- au semnat consimţământul informat după ce li s-a explicat scopul şi procedurile cerute de protocol ;
- capacitate de înţelegere.

Criteriile de excludere sunt enumerate mai jos :
- dacă erau diagnosticaţi cu sindrom de dependenţă la alcool sau la alte substanţe ;
- internaţi împotriva voinţei lor ;
- femeie însărcinată sau care alăptează ;
- istoric de alergie la haloperidol, olanzapina, sertindol şi quetiapina sau la excipienţii acestora ;
- istoric de rezultate pozitive la testele serologice pentru virusul hepatitei B, C şi HIV;
- istoric de sindrom neuroleptic malign ;
- istoric de glaucom cu unghi închis ;
- orice afecţiune somatică neechilibrată ;
- leucopenie ;
- orice probleme cardiovasculare, respiratorii, neurologice, renale, hepatice, endocrine, hematologice sau imunologice netratate ;
- istoric de malignitate în ultimii 5 ani ;
- diskinezie moderată sau severă în timpul înrolării ;
- ideaţie suicidară sau tendinţe violente în perioada de titrare a medicaţiei ;
- lipsa eficacităţii uneia dintre substanţele cercetate în antecedente.

Design-ul studiului

Design-ul studiului a fost structurat astfel : vizite săptămânale în prima lună, apoi vizitele au fost lunare până la 1 an. Retragerea pe parcursul studiului s-a făcut în urma :
- deciziei medicului în cazul unor evenimente adverse severe sau modificări clinic semnificative a unor parametri de laborator ;
- deciziei pacientului ;
- modificării sau întreruperii medicaţiei de studiu, indiferent de motiv (absenţa eficacităţii, solicitarea pacientului, sarcină etc.).

Perioada de studiu I : screening-ul

Vizita 1 (V1) (durata : 2 zile) Rezultatele testelor screening trebuie obţinute şi interpretate înainte de cea de a doua vizită (V2).

Pentru ca subiectul să poată continua participarea în studiu, a fost necesar ca toate criteriile de înrolare să fie îndeplinite la V2. Nu a fost obligatorie finalizarea testelor într-o singură zi. Pentru completarea tuturor procedurilor pot fi alocate două zile.

După V1 se va întrerupe orice medicaţie cu efect psihotrop ; invitarea pacientului de a lua parte la acest studiu şi semnarea consimţământului informat ; consemnarea datelor de identificare ; diagnosticul ; antecedentele personale patologice ; antecedentele heredo-colaterale ; anamneza socio-profesională ; verificarea parametrilor vitali (tensiune arterială, puls, temperatură) ; măsurarea taliei şi a greutăţii ; înregistrarea ECG ; test de sarcină (pentru femei) ; examene de laborator (ionogramă, glicemie, hemogramă, TGP, TGO, colesterol, uree, creatinină).

Perioada de studiu II

Pe parcursul acestei faze pacienţii au primit haloperidol 5 - 10 mg/zi, sertindol 12- 16 mg/zi, olanzapină 5 - 20 mg/zi, quetiapină 600-800 mg/zi. Doza zilnică eficace a fost stabilită prin titrare. Înregistrarea ECG a fost realizată la fiecare vizită.

Analiza statistică

Deoarece numărul de subiecţi este redus, eşantioanele sunt mici, repartiţia caracteristicilor studiate este normală, iar de la o vizită la alta scade numărul pacienţilor din eşantion, am aplicat testul *t-Student*. Testul reprezintă pragul ce separă descriptivul de începutul cercetării analitice.

Datele au fost introduse şi prelucrate cu ajutorul funcţiilor statistice din *Microsoft Excel* (Microsoft Corp.) şi pachetul de analiză statistică *SPSS 14.0* (SPSS Inc.).

Rezultatele sunt exprimate ca media plus sau minus deviaţia standard (DS). S-a considerat pragul de semnificaţie statistică p(Sig.) $< 0,05$ (fig. 1).

Din anii ’60, când au fost raportate primele cazuri de morţi subite la pacienţi aflaţi

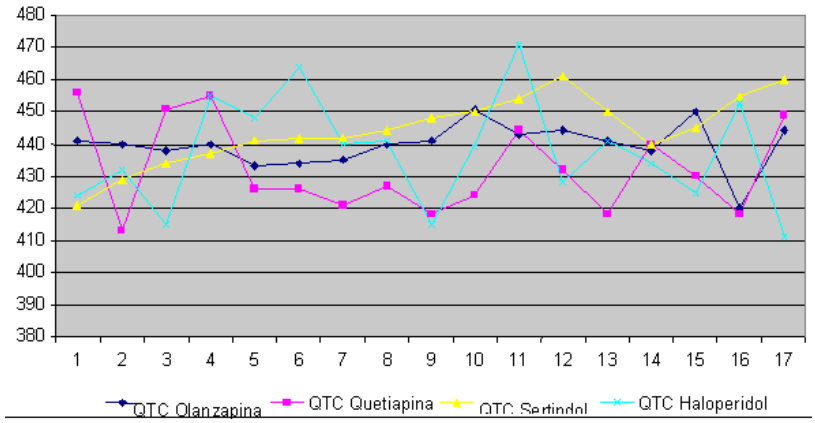

Fig. 1. Monitorizarea ECG pe parcursul studiului (variaţia intervalului QTc la cele patru antipsihotice)

în tratament cu antipsihotice, a existat o preocupare crescândă a comunităţii psihiatrice în legătură cu efectele adverse cardiovasculare ale antipsihoticelor. În anii ’90 a devenit clar că mesoridazina, un antipsihotic convenţional, poate provoca torsada vârfurilor (6).

Torsada vârfurilor reprezintă un tip specific de tahicardie ventriculară, caracterizată printr-un aspect polimorf al complexelor QRS, care variază în amplitudine şi în lungimea ciclului, creând aspectul unor oscilaţii în jurul liniei de bază. Acest ritm este precedat de o prelungire marcată a intervalului QT, adesea >600 ms. Intervalul QT, măsurabil pe ECG, include atât durata depolarizării, cât şi a repolarizării ventriculare şi variază invers proporţional cu frecvenţa cardiacă. Intervalul QT corectat în funcţie de frecvenţa cardiacă se calculează conform formulei QTc = QT/RR 0,5. Torsada vârfurilor poate progresa către fibrilaţie ventriculară şi moarte subită. Prelungirea intervalului QTc >450 ms sau o creştere cu >10% a intervalului QTc faţă de momentul iniţierii terapiei cu antipsihotice sunt privite ca indicatori ai unui risc crescut de apariţie a torsadei vârfurilor (7,8).

Din acest motiv a fost realizată monitorizarea ECG pe parcursul studiului, asigurând un profil de siguranţă din punct de vedere cardiovascular pentru pacienţii înrolaţi. Se observă că cea mai mare creştere a intervalului QTc a fost înregistrată în cazul haloperidolului la vizita 11 (471 ms). Sertindolul determină o creştere a intervalului QTc până la vizita 12, apoi urmează o scădere a acestor valori până la finalul protocolului unde înregistrăm din nou o creştere a valorilor. În ceea ce priveşte quetiapina, s-au raportat cazuri rare de prelungire a intervalului QTc, în timpul desfăşurării protocolului. Acestea au fost înregistrate la doi pacienţi din acest lot care şi-au administrat doze mai mari decât cele prevăzute în protocol.

În concluzie, toate antipsihoticele atipice au fost asociate cu o uşoară prelungire a intervalului QTc. Această prelungire nu s-a constituit într-un risc veritabil pentru pacient, din punct de vedere vital, ceea ce ne îndreptăţeşte să utilizăm cu încredere medicaţia antipsihotică. Global, beneficiile sunt semnificativ superioare, pacientul funcţionează, este reintegrat, motiv pentru care riscul cardiogen îl considerăm poate exagerat.

Prudenţa este oportună în prescrierea medicaţiei antipsihotice. Excesul de prudenţă defavorizează gestionarea cazului. Nu trebuie să uităm că tratamentul în schizofrenie este cronic şi obligatoriu va fi indicat un antipsihotic. Toate ghidurile recomandă

în prima linie un antipsihotic atipic, iar cele utilizate în studiul nostru fac parte din protocolul obişnuit de tratament. De asemenea, trebuie să reţinem că nici un antipsihotic folosit nu a fost asociat cu torsada vârfurilor.

NOUTĂŢI

ANOMALII CITOGENETICE DECELATE LA PACIENŢII CU AZOOSPERMIE NON-OBSTRUCTIVĂ ŞI OLIGOSPERMIE SEVERĂ

Koşar şi Ozcelik au analizat 115 bărbaţi cu sterilitate (92 cu azoospermie şi 23 cu oligospermie severă) care au fost investigaţi citogenetic - înaintea utilizării unei tehnici de reproducere asistată – la Spitalul din Isparta, Turcia. A fost utilizat şi un grup martor constituit din 60 de bărbaţi cu ferilitate normală. Analiza cromozomială, efectuată la toţi pacienţii, s-a bazat pe culturi de limfocite din sângele periferic. De asemenea, la toţi pacienţii, au fost efectuate teste hormonale (LH, FSH, testosteron şi prolactina) şi ecografie testiculară. Prevalenţa anomaliilor cromozomiale decelate a fost de 4,3% (5/115) şi a inclus 4 cazuri cu sindrom Klinefelter şi 2 cazuri cu disgenezie testiculară, 46,XX. Toate anomaliile au fost decelate la pacienţi cu azoospermie (5,4% - 5/92). Bărbaţii cu oligospermie severă şi cei din lotul martor nu au prezentat anomalii cromozomiale. A existat o diferenţă semnificativă între valorile serice ale FSH, LH şi ale volumului mediu testicular la pacienţii cu azoospermie şi oligospermie severă, comparativ cu lotul martor ($p < 0,05$), precum şi între pacienţii cu azoospermie şi cei cu oligospermie ($p < 0,05$). Frecvenţa crescută a anomaliilor cromozomiale decelate la bărbaţii cu sterilitate, sugerează necesitatea efectuării de rutină a analizei cromozomiale şi a acordării sfatului genetic, în cazul acestor pacienţi, înaintea aplicării unei tehnici de reproducere asistată (Koşar PA, Ozçelik N, Koşar A. Cytogenetic abnormalities detected in patients with nonsobstructive azoospermia and severe oligozoospermia. *J Assist Reprod Genet* 2010 ; 27 (1) : 17-21).

LONG-TERM SURVIVAL IN HER2-POSITIVE BREAST CANCER WITH BRAIN METASTASES. CASE REPORT (Abstract): We report the case of a 41-year-old woman diagnosed in October 2014 with bone-only metastatic HER2-positive breast cancer, who developed brain metastases (BM) 15 months after the initial cancer diagnosis. The patient initially received palliative chemotherapy with Paclitaxel, discontinued due to allergic reactions, and targeted therapy with Herceptin. BM were treated with antalgic radiotherapy and bisphosphonates. After the occurrence of secondary brain lesions, the patient underwent palliative whole-brain radiotherapy (WBRT) and systemic treatment with Capecitabine and Lapatinib from February 2016. In February 2018, Lapatinib was replaced with Trastuzumab emtansine, after the approval of this drug in Romania. Due to the deterioration of patient's clinical state, in October 2018 the administration of Trastuzumab emtansine was postponed, the patient received symptomatic treatment until she died 49 months after the diagnosis and 34 months after the occurrence of BM, respectively. The authors report this case in order to illustrate the importance of the multidisciplinary management of BM that had substantially improved the neurological symptoms and survival in this patient. Early recognition and appropriate therapy of breast cancer is imperative as it may be crucial for the outcome. **Keywords**: BREAST CANCER, BRAIN METASTASES, RADIOTHERAPY, TARGETED THERAPY.

Brain metastases (BM) are a significant cause of mortality in cancer patients, 20% to 40% of cancer patients will develop BM during their illness (1). The primary tumors that usually cause BM are lung cancer in 50% of cases, followed by breast cancer in 15-25% and melanoma in 5-20% (2).

Currently, about 20%-45% of patients with Her2-positive metastatic breast cancer will develop parenchymal BM (3). Moreover, in the case of Her2-positive cancers the extracerebral disease is controlled in 50% of cases at the diagnosis of BM.

Treatment for BM includes surgical resection, followed by stereotactic radiosurgery (SRS) or WBRT in a limited number of lesions. However, the optimal treatment remains controversial (4).

CASE REPORT

On October 2014, a 41-year-old obese, nulliparous woman presented at the Regional Institute of Oncology Iasi with a mass in her right breast, without palpable axillary nodes.

She had no significant past medical or family history and was not taking any medication. She admitted to drinking occasionally at social events but denied having ever smoked.

Mammography of her right breast (fig. 1) revealed a 1.8/1cm mass with associated microcalcifications.

A core-needle biopsy was taken from the lesion and highlighted an invasive ductal carcinoma overexpressing HER-2 (immunohistochemical score 3+) with low positive estrogen and progesterone receptors. Furthermore, in this case the Ki-67 index was extremely high, 60%.

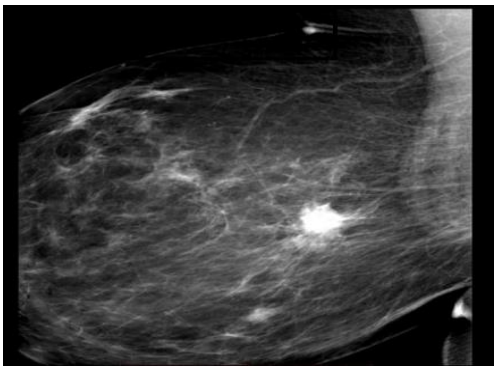

Fig. 1. Right mediolateral oblique view on screening mammogram revealed a focal asymmetry in the right lower outer quadrant with microcalcifications.

The initial chest-abdomen-pelvis computed tomography (CT) examination revealed an abnormal grow thin the lower outer quadrant of the right breast with extension to the aponeurosis of the pectoral muscle (T2), bone metastases in different sites (sternum, lumbar spine L2-L6, sacrum and bilateral femoral), multiple metastatic adenopathies (right axillary lymph nodes, ipsilateral internal mammary nodes, mediastinal and bilateral hilar lymphadenopathy) (N2). Clinical disease stage was assessed as cT2N2M1, stage IV.

Lactate dehydrogenase and alkaline phosphatase levels were elevated.

Serum study showed a normal level of cancer antigen 15-3 (15 U/mL).

Following the oncology consultation, palliative chemotherapy was started. Treatment with Paclitaxel (175 mg/m^2 every three weeks), discontinued in January 2015 due to third degree peripheral neuropathy, and targeted therapy with Trastuzumab (8 mg/kg iv loading dose, followed by 6 mg/kg every three weeks), from January 2015 to June 2017 were initiated.

For the bone metastases the patient received antalgic radiotherapy and treatment with 4 mg zoledronic acid every 3 weeks.

In January 2016 the patient was admitted for progressively worsening headaches and vomiting. A brain scan revealed multiple secondary parenchymal brain and cerebellar lesions (fig. 2).

WBRT (20 Gy / 5 fractions / 4 Gy / fraction) was performed. The neurological symptoms subsided very quickly. Otherwise, staging exams showed that all bone lesions were stable, and the primary tumor had not increased in size.

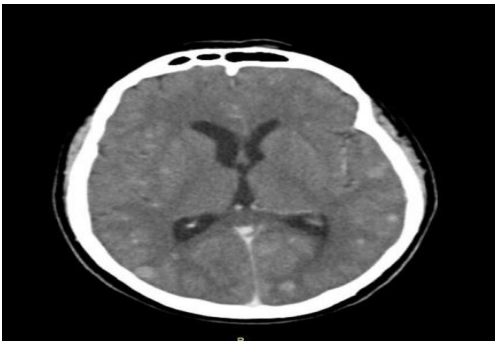

Fig. 2. CT scan of the brain showed multiple brain metastases.

Treatment with capecitabine 2,000 mg/m^2/ day (days 1-14) and lapatinib 1,250 mg/day was then initiated in February 2016. In December 2017, the patient underwent a whole-body CT scan that revealed the progression of brain metastases.

In February 2018, Lapatinib was replaced with Trastuzumab emtansine (3.6 mg/kg, every three weeks) following its approval in Romania. The therapy was well

tolerated without serious adverse events.

The patient's cardiac function was evaluated from the beginning of treatment by echocardiography once every 3 months. The first measurement of the Left ventricular (LVEF) was 65% and has been maintained during the treatment.

In October 2018 the patient presented a rapid and significant decline in general health status despite intensive symptomatic therapy. Unfortunately, our patient did not recover from her moribund neurological state and died several weeks later.

DISCUSSION

In this case, the objective of the multidisciplinary team in the management of BM was twofold: survival and quality of life.

HER2-positive tumors occur in 25% of all breast cancers (5). The human epidermal growth factor receptor 2 (HER2/ErbB2) is a member of the ErbB family of tyrosine kinase receptors which regulates normal cell growth. Dysregulated HER-2 activation supports tumorigenesis via cell proliferation, migration, survival, and angiogenesis (6). The risk of developing BM is higher among patients with overexpression of HER2-positive (7).

Median time from breast cancer diagnosis to BM is about 3 years with the longest reported interval of 97 months (8). Our patient developed BM 15 months after the initial diagnosis of breast cancer.

Bones are the most common secondary site of metastatic breast cancer, followed by the lungs, brain and liver (9, 10). Our patient was initially diagnosed with bone-only metastatic breast cancer that had later spread to the brain. Curiously, the patient did not develop other metastatic sites and the already present bone metastases remained stable, showing no progression.

In case of BM, the blood-brain barrier undergoes alterations around the metastatic sites. Radiotherapy can be used to increase the permeability of the blood-brain barrier and to favor the passage of various chemotherapeutic agents.

Ogawa *et al.* (11) reported that in 45 patients with breast cancer and BM, improvements in neurological symptoms were obtained in 35 patients (77.8%) using palliative radiotherapy without systemic chemotherapy. Therefore, the therapeutic strategy focused on BM allows the patient to regain a good quality of life.

Lapatinib, a dual inhibitor of the intracellular tyrosine kinase domain of HER1 and HER2, is expected to cross the blood brain barrier due to its very low molecular weight. Its efficacy has been investigated in combination with capecitabine in patients with previously untreated brain metastases from HER2-positive metastatic breast cancer (Landscape study) (12).

In the EMILIA study (13), Trastuzumab emtansine was compared with lapatinib plus capecitabine in advanced HER2- positive metastatic breast cancer pre-treated with Trastuzumab. Trastuzumab emtansine prolongs overall survival in patients with pre-existing BM (26.8 *vs.* 12.9 months, p=0.008).

Performance status (PS) is a strong independent prognostic factor for survival in breast cancer patients with BM (14). Throughout the disease course, our patient had a relatively good quality of life, the ECOG score being 1-2. Quality of life has been one of our objectives.

CONCLUSIONS

In this case, despite the unfavorable prognosis of breast cancer with BM, the multidisciplinary management had substantially improved the neurological symptoms and survival of the patient.

Thus, the patient died 49 months after

the initial diagnosis and 34 months after the occurrence of BM, respectively. Early detection of breast cancer remains the primary defense to prevent the development of this life-threatening disease.

CORRELATIONS BETWEEN IADL SCALE AND CLINICAL PARAMETERS IN SEVERE-TO-VERY SEVERE COPD PATIENTS (Abstract): **Aim**: To identify the clinical parameters correlated with the Lawton Instrumental Activities of Daily Living (IADL) scale in severe-to-very severe COPD patients, admitted for an inpatient pulmonary rehabilitation program (PRP). **Material and methods**: We conducted a retrospective analytical study in 84 patients with GOLD 3 and GOLD 4 stage COPD, consecutively admitted to Iasi Pulmonary Rehabilitation Clinic, from January 2016 to December 2017, for an inpatient PRP. In addition to spirometry, the following functional evaluations were carried out: Lawton Instrumental Activities of Daily Living (IADL) scale, dyspnea assessment (on Modified Medical Research Council - mMRC and Borg scale), and COPD Assessment Test (CAT). **Results**: The study included 84 COPD patients, mean age 66.98±10.06 years and mean FEV_1 37.04±9.03% of predicted value. Mean values of FEV_1, dyspnea score on mMRC ($p=0.01$), and Borg scale ($p<0.001$) were significantly lower in GOLD 4 stage COPD. Median values of CAT and IADL scores were comparable, irrespective of gender or severity of COPD. There were negative correlations between IADL score and age ($r = -0.25$; $p=0.02$), mMRC dyspnea score ($r = -0.46$; $p<0.001$), Borg dyspnea score ($r = -0.412$; $p<0.001$), and CAT score ($r = -0.427$; $p<0.001$). In multivariate analysis, only age and the mMRC score remained significantly associated with IADL score. **Conclusions**: Pulmonary rehabilitation should be tailored for COPD patients with cognitive impairment, according to the severity of the disease and its assessment should be incorporated as a clinical outcome in the management of this chronic condition. **Keywords**: CHRONIC OBSTRUCTIVE PULMONARY DISEASE, PULMONARY REHABILITATION, IADL.

Chronic obstructive pulmonary disease (COPD) is a multi-systemic disease and a leading cause of morbidity and mortality worldwide. Self-management of this chronic condition as well as enrollment in pulmonary comprehensive rehabilitation programs are fundamental to coping with this invalidating disease.

Cognitive impairment and psychiatric disorders are well-recognized co-morbidities of COPD, with a high prevalence of 32% (1, 2). Neurotoxicity and multiple cerebral insults related to smoking, occupational exposure, hypoxia, and

inflammation lead to deficits in cognitive domains of memory, attention, motor and executive functions (3, 4, 5).

Current therapeutic strategy in COPD, according to the guidelines, requires the active involvement of the patients in smoking cessation, physical exercise, and pulmonary rehabilitation (6-10). Evaluation of cognitive abilities and disabilities may predict the amplitude of behavioral changes.

Lawton's Instrumental Activities of Daily Living (IADL) Scale was developed to assess the activities used for functioning in community settings, named "instrumental activities of daily living" (IADLs), unlike basic activities, like bathing, eating, toileting, named "activities of daily living" (ADLs) (11). The capacity to handle these more complex activities is lost before basic activities, so it allows identification of functional decline or signals the need for further assessment in older adults or other individuals, like those with chronic invalidating diseases, as COPD (11, 12).

The aim of our study was to identify the clinical parameters correlated with the Lawton Instrumental Activities of Daily Living (IADL) scale in severe-to-very severe COPD patients, admitted for an inpatient pulmonary rehabilitation program.

MATERIAL AND METHODS

We conducted a retrospective analytical study, in 84 patients with severe-to-very severe COPD, consecutively admitted to Iasi Pulmonary Rehabilitation Clinic, from January 2016 to December 2017, for an inpatient pulmonary rehabilitation program. Data were extracted from the medical records, ensuring security and confidentiality, in accordance with current regulations.

The inclusion criteria were the diagnosis of COPD, meeting the GOLD criteria for diagnosis and classification of severity, corresponding to stage 3 or 4 of the disease: suggestive symptoms (dyspnea, chronic cough, sputum production, history of exposure to risk factors for the disease), the presence of a post-bronchodilator $FEV_1 < 0.70$, and a $30\% \leq FEV_1 < 50\%$ predicted for GOLD 3 stage and $FEV_1 < 30\%$ predicted for GOLD 4 stage (13). Exclusion criteria were the diagnosis of mild-to-moderate COPD (GOLD 1 and GOLD 2 stage) and patients with missing values that might affect statistical results.

In addition to spirometry, the following functional evaluations were carried out: Lawton Instrumental Activities of Daily Living (IADL) scale, dyspnea assessment (on Modified Medical Research Council - mMRC and Borg scale), and COPD Assessment Test (CAT) (14).

The Lawton IADL scale (11) contains 8 items, measuring eight domains, rated from 0 (low functioning) to 8 (high functioning) and was administrated by a written questionnaire; scale took approximately 10 to 15 minutes to provide the answers, in the presence of a nurse, if additional explanations were required.

All subjects completed the CAT, consisting of 8 items, graded from 0 to 5 and designed to measure the global impact of COPD on a patient's life, with the range of CAT score from 0-40 (10, 14). The severity of dyspnea was assessed on mMRC and Borg scale of perceived exertion, which runs from 0-5, and 0-10, respectively.

Statistical analysis. The data were processed using *SPSS 16.0* software (SPSS Inc., Chicago, IL) and *Microsoft Excel* 2016 for *Windows*. The parameters and their frequencies were analyzed and the statistical significance of differences between groups (according to gender and

GOLD stage of COPD) was assessed by Student *t-test* for parametric variables and Kruskal-Wallis H or Sign-test for ordinal and nominal variables. Spearman's rank correlation coefficient was used for investigating the relationship between variables. The significance was set to a p value of 0.05 or less.

RESULTS

The study included 84 COPD patients, mean age 66.98±10.06 years, with the predominance of male gender (68 male patients - 81%), and mean FEV_1 37.04±9.03% of predicted value. Distribution according to the GOLD stage and gender shows no significant difference according to GOLD stage (45 patients stage 3 *vs.* 39 patients stage 4; p=NS) (tab. I).

TABLE I

Distribution of cases according to the GOLD stage of COPD and gender

Gender	GOLD 3	GOLD 4
Female (no pts.)	12	4
Male (no pts.)	33	35
TOTAL	45 patients	39 patients

Assessment of dyspnea on revised Borg scale allowed patients to subjectively rate their level of exertion and revealed aggregation of cases (55 patients, 65.47%) in the high severity area of perceived exertion, from 7 (very severe) to 10 (maximal) (fig. 1).

mMRC Dyspnea Scale assesses baseline functional impairment of individuals with COPD and 73 patients (86.9%) had 4 and 5 degrees of severity (fig. 2). There were significant differences between the two severity groups regarding dyspnea score on mMRC (p=0.01) and Borg scale (p<0.001), favoring stage GOLD 3.

Calculation of IADL score and the distribution of cases according to the results has shown surprising results, more than half of the cases (50 patients, 59.52%) having scores ranging from 6 to 8 (tab. II).

Mean values of FEV1 were significantly lower in GOLD 4 stage COPD as well as dyspnea score on mMRC (p=0.01) and Borg scale (p<0.001) but comparable between diseased men and women. Median values of CAT score and IADL score were comparable, irrespective of gender or severity of COPD (tab. III).

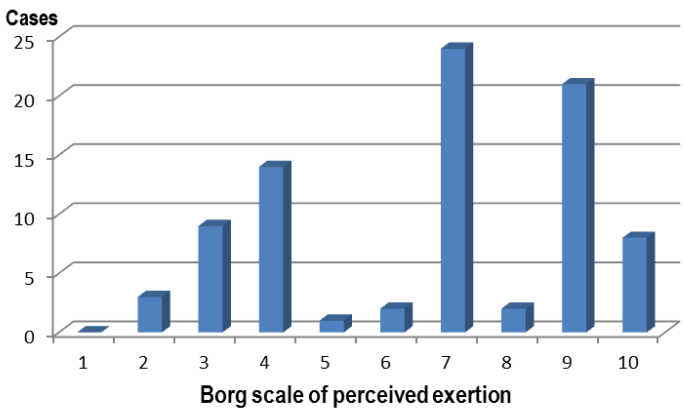

Fig. 1. Distribution of cases according to the severity of dyspnea on Borg scale

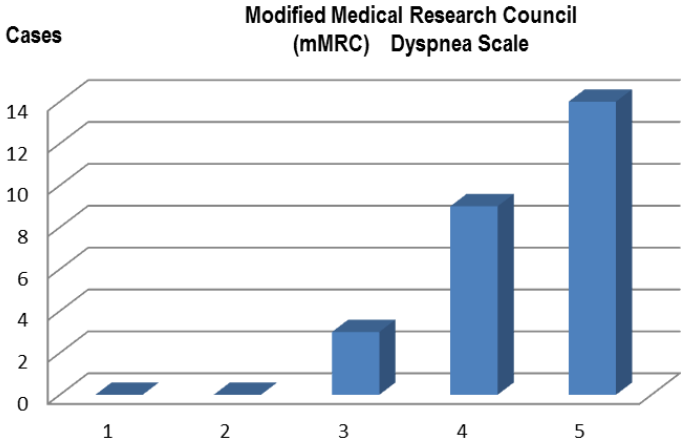

Fig. 2. Severity of dyspnea on mMRC scale

TABLE II

Distribution of cases according to total IADL score and GOLD stage of COPD

	IADL score (total)								
GOLD stage (no pts.)	0	1	2	3	4	5	6	7	8
GOLD 3	0	0	2	2	6	4	15	4	12
GOLD 4	2	3	3	4	3	5	9	5	5
Total patients	2	3	5	6	9	9	24	9	17

TABLE III

Mean values of FEV_1 according to gender and GOLD stage of COPD

		FEV_1 (% predicted)	p	CAT score (median value)	p	IADL score (median value)	p
Gender	Female	38.18±9.86%	NS	26 (18-37)	NS*	6 (0-8)	NS*
	Male	36.77±8.88%		28 (9-39)		6 (0-8)	
GOLD stage	GOLD 3	42.17±5.91%	<0.001	26 (18-37)	0.471* (NS)	6 (2-8)	0.457* (NS)
	GOLD 4	31.12±8.40%		28 (15-39)		5 (0-8)	

*Non-parametric tests

There is a significant correlation between IADL score and age (r = -0.25; P=0.02), mMRC dyspnea score (r = -0.46; P<0.001), Borg dyspnea score (r = -0.412; P<0.001), and CAT score (r = -0.427; P<0.001), for the studied group but in a negative or inverse relationship; that means the higher scores on the dyspnea scale, corresponding to a more severe dyspnea, are correlated with lower IADL scores, signifying a more prominent disability of the patient. In multivariate analysis, using the parameters significantly associated with IADL score in univariate analysis: age,

mMRC score, CAT 2 item - sputum production, CAT 3 item - chest tightness, CAT 6 item - self-confidence regarding living home, and CAT total, only age, and the mMRC score remained significantly associated with IADL score.

DISCUSSION

Multiple studies (3, 15-17) demonstrated a significant relationship between cognitive impairment and disability in COPD patients; disability is present in all disease stages, but it is related to disease severity. Braido *et al.* (15) showed that in COPD patients disability can be identified in all stages of the disease, the most relevant complaint being dyspnea, quantified on scales like MRC scale (15, 18), consistent with the final outcome of our research.

Our study revealed the aggregation of most of the cases in the more severe area of perceived breathlessness, both through estimation on Borg scale and mMRC scale, with this capital symptom being significantly worse in GOLD 4 stage of COPD, as expected.

When assessing the study group through CAT questionnaire, the median value of total CAT score was the same across the two GOLD stages, confirming that the burden of COPD on major symptoms and daily activities is not related in a linear manner to the severity of the disease, but is influenced by individual and environmental factors.

The distribution of cases according to total IADL score was somewhat surprising, 59.52% of the patients having scores ranging from 6 to 8 that means a high degree of functionality and independence among the COPD individuals addressed to the pulmonary rehabilitation program, despite the severity of the disease. A possible explanation would be the relatively low mean age (66.98±10.06 years) of the studied group and the involuntary selection of the most independent patients as candidates for pulmonary rehabilitation programs, the older and dependent patients being neglected in this regard both by themselves, relatives or family doctor. Still, the inverse or negative relationship between IADL score, age, and severity of dyspnea on mMRC and Borg scale means that the older the patient and the more severe the shortness of breath the lower the IADL score, meaning a more severe functional impairment.

Regular physical activity has proven positive cognitive outcomes, along with improved exercise tolerance and reduced symptoms like fatigue and dyspnea but requires ongoing sustained participation in regular exercise program (3, 19, 20) so that it is very important to first assess then develop support systems that will enable enrollment of COPD patients in pulmonary rehabilitation programs.

Our results showed a significant correlation between both IADL and CAT scores, but in multivariate analysis only age and shortness of breath remained significant contributors, stressing the necessity of tailoring the rehabilitation program to the individual's capacity and the degree of cognitive impairment and functioning.

CONCLUSIONS

Our study emphasizes the importance of assessing the functional capacity as well as the cognitive impairment in severe-to-very severe COPD, which seems to be related to age and dyspnea severity, regardless of the stage of disease, in such patients. Consequently, given the relevance of IADLs to the life of patients with COPD, pulmonary

rehabilitation should be adapted for COPD patients with cognitive impairment, according to the severity and its assessment should be incorporated as a clinical outcome in the management of this chronic disease.

CHALLENGES IN THE MORPHO-FUNCTIONAL CHARACTERIZATION OF DILATED CARDIOMYOPATHY

T. Braniste[1*], Gh. Braniste[2], V. Dorgan[2]
"Nicolae Testemitanu" State University of Medicine and Pharmacy, Chisinau
Faculty of Medicine
1. Clinic of Medical Semiology
State University of Physical Education and Sport, Chisinau
2. The Theoretical Bases of Physical Culture

CHALLENGES IN THE MORPHO-FUNCTIONAL CHARACTERIZATION OFDILATED CARDIOMYOPATHY (Abstract): **Aim** refining the diagnosis of dilated cardiomyopathy (DCM) and improving diagnostic criteria. **Material and methods**: The study group consisted of 655 patients with heart failure (HF), NYHA class I-IV, of which 358 patients with DCM, 87 patients with inflammatory cardiomyopathy (ICM) and 210 patients with ischemic cardiopathy/ischemic cardiomyopathy (ICP/ICMP).The control group consisted of 120 healthy individuals. The diagnostics of DCM, ICM and ICP/ICMP comply with the recommendations of the current guidelines. **Results:** The radiopaque ventriculography showed increased ventricular volume, diffuse decrease of myocardial contractility and low ejection fraction of the left ventricle (LV). Perfusion abnormalities recorded in DCM patients (36.2%) did not differ significantly from those recorded in ICM (34.8%) and ICP/ICMP patients (40.3%). Holter monitoring revealed electrical instability of the myocardium in DCM and ICM patients, without statistically significant differences. Mitochondrial respiration study in DCM patients revealed a lower mean content of creatinekinase-15 and a greater content of creatinkinase MB-27 compared to healthy control group, and a marked impairment in acceptor control and creatine-stimulated mitochondrial respiration. The levels of myosin light chain kinase and related protein kinase in DCM and ICM were increased by 70% and 52%, respectively. We also have noticed a significant increase in annexin V and annexin VI levels in the myocardium of DCM patients compared to healthy control group: 122 ± 5% ($p < 0.05$) and 119 ± 5% ($p < 0.05$), respectively. **Conclusions:** We have conducted a complex cardio-vascular evaluation, using modern, high sensitivity and specificity techniques, with the purpose of identifying functional and structural elements, which will allow us to refine the DCM diagnostic. The results of our study grant a better understanding of the electrical and mechanical phenomena that underlie the functional and structural changes encountered in DCM. We thoroughly evaluated a series of morphological, morphometric and bioenergetic parameters of the myocardium, we determined intracardiac hemodynamic parameters and quantified the contractile status of the heart. Although we have identified significant morpho functional abnormalities, we have concluded that they have no specificity for DCM. These changes may rather be considered the expression of advanced disease status. **Keywords:** CARDIOMIOPATHY, HEART FAILURE ANNEXINS, ENERGY METABOLISM.

It has been more than six decades since Goodwin JF, based on his research on the peculiarities of morphological changes in the myocardium, proposed the definition

and the first classification of cardiomyopathies (1), which was adopted, without any change in principle, by the World Health Organization (WHO) and by the International Society and Federation of Cardiology. Over the years, due to their impact on medical practice, cardiomyopathies have been the subject of a tremendous number of clinical and experimental investigations, focused on various aspects of the problem (2, 3, 4, 5). But a question still remained: is dilated cardiomyopathy (DCM) a distinct nosological entity, which univocally implies a known etiology, or is it a syndrome, the result of various pathological processes, whose causes are not established or are not yet conclusively demonstrated?

Finding an answer to this question would make possible to clarify the definition either of DCM as a nosological form or of the probable DCM subtypes, conditioned by already established causal factors. Hence, it will become possible to characterize more accurately the syndrome's subtypes, to develop diagnostic criteria and construct a differential diagnosis (not only with other diseases, but also between DCM subtypes), as well as to find targeted, pathogenic and etiotropic treatments.

The aim of the study was to find answers to at least some of these problems, based on our experience accumulated over 20 years of studying the different aspects of DCM. To achieve this goal, we performed a thorough analysis and corroborated the multiple data obtained from our clinical and experimental studies.

MATERIAL AND METHODS

We included in our study 655 patients with heart failure (HF), NYHA class I-IV. The study group consisted of 358 patients with DCM [38.3 ± 0.6 years, 313 (87.4%) males and 45 (12.6%) females], 87 patients with inflammatory cardiomyopathy (ICM) [34.6 ± 1.3 years, 70 (80.5%) men, 17 (19.5%) women], and 210 patients with ischemic cardiopathy/ischemic cardiomyopathy (ICP/ICMP) [52.5 ± 1.2 years, 110 (91.7%) men, 10 (8.3%) women] (Tab. I). As inflammatory cardiomyopathy (myocarditis) is defined as inflammation of the heart muscle associated with impaired function of the myocardium regardless of its etiology, we enrolled in this group patients with infectious myocarditis (mainly of viral etiology) and also patients with myocarditis accompanying autoimmune disease (noninfectious myocarditis).

TABLE I

Distribution of patients according to study group and NYHA class

	DCM		ICM		IC/ICMP	
NYHA class	No.	%	No.	%	No.	%
I	56	15.7	24	27.5	42	20.0
II	122	34.1	28	32.2	88	41.9
III	162	45.3	28	32.2	80	38.1
IV	18	5.0	7	8.0	0	0

Clinical diagnosis of DCM and ICM was made in accordance with WHO expert group recommendations (1984, 1995, 2010). Positive and differential diagnostic were based

on coronary angiography, morphological and morphometric analysis of subendomycocardial biopsy samples, and in 79 (22.1%) cases based on autopsy reports. Overall, the clinical diagnosis of DCM and ICM was confirmed in 248 (74.9%) patients, respectively 60 (68.9%) patients, so we had a good anatomical-clinical correlation. We also selected a control group, consisting of 120 healthy individuals [mean age: 30.2 ± 1.4 years, of which 110 (91.7%) men and 10 (8.3%) women].

RESULTS

For all 79 HF patients autopsied we performed the macroscopic analysis of the hearts and the microscopic analysis of the myocardial tissue taken from the right ventricle (RV) free wall and from each wall of the left ventricle (LV). *Macroscopic analysis* revealed in all DCM patients the typical enlargement of all heart chambers, especially the left sided ones. Overall, heart mass exceeded normal values. Individual values ranged from 450 to 1300 grams. LV, RV and IVS masses, weighted separately, were also substantially increased, demonstrating total myocardial hypertrophy in all DCM patients. Microscopic examination revealed myocardial sclerosis. *Sclerotic changes* of the myocardium occurred most frequently in the LV (92.3%), mainly in the LV free walls (86.5%), and rarely in RV free wall (69.2%). In general, we identified diffuse, microfocal and diffuse microfocal sclerosis. Macrofocal sclerosis was mainly detected in LV (21% cases) and very rare in RV and IVS.

Invasive hemodynamic data were acquired in 104 patients with severe HF (NYHA class III-IV). *Central hemodynamic data* in patients with DCM revealed increased cardiac chamber volumes and pressures, with decreased ventricular ejection fraction. We also performed a comparative analysis of the mean values of the hemodynamic parameters in DCM, ICM and ICP/ICMP patients.

RAP - right atrial pressure; RVEDP - right ventricular end-diastolic pressure; PASP - pulmonary artery systolic pressure; PADP - pulmonary artery diastolic pressure; PAP - pulmonary artery pressure; LVEDP - left ventricular end-diastolic pressure; LVESV - left ventricular end-systolic volume; LVEDV - left ventricular end-diastolic volume; LVIB - left ventricular index-beat; LVEF - left ventricular ejection fraction; LVFSV - left ventricular fiber shortening velocity; RVESVI - right ventricular end-systolic volume index; RVEDVI - right ventricular end-diastolic volume index; RVIB - right ventricular index-beat; RVEF -right ventricular ejection fraction; NS - non significant.

During left cardiac catheterization, we assessed not only hemodynamic parameters, but also LV wall motion and contractility. Segments visible in the angiographic right anterior oblique view are five: anterobasal, anteromedial, apical, inferomedial and posterobasal. The study of *regional LV myocardial contractility* in all 5segments revealed similar changes in patients with DCM and ICM. Based on the percentage reduction of the surface in all segments, we concluded that the contractility was diffused decreased. The magnitude of the decrease has varied between 22 ± 2% to 31 ± 2% in DCM patients and 24 ± 3% to 32 ± 2% in ICM patients compared to controls. Regional LV contractility analyzed by radionuclide ventriculography did not differ between DCM and ICM patients.

The incidence and the type of arrhythmia were also evaluated. No significant

differences were observed between patients with DCM and ICM. When we adjusted by HF severity, the type and the incidence of heart rhythm and conduction abnormalities were higher in DCM patients than in ICM patients. However, the statistical significance was obtained only for ventricular ectopic beats ($p < 0.01$).

TABLE II

Central hemodynamic indices in patients with DCM, ICM and ICP/ICMP according to radiopaque ventriculography data

	DCM (n = 57)	ICM (n = 23)	ICP/ICMP (n = 24)	Statistical significance (p)
Mean RAP (mmHg)	5.9 ± 0.5	5.3 ± 1.1	8.0 ± 1.0	NS

RVEF (%)	33.0 ± 1.0	34.0 ± 1.9	37.0 ± 2.7	NS

Coronarography was performed on all patients catheterized on the left heart. In patients with DCM, sinuous coronary arteries were found. When coronary dilators were administered, increased resistance and decreased coronary artery dilation were noted. The dilation index in DCM was lower than in the control group, 8.0 ± 1.2 and 21.0 ± 1.2, respectively ($p<0.001$). No statistically significant differences in indices were

noted between DCM and ICM patients.

TI-201 myocardial scintigraphy at rest showed that the highest level of myocardium radiotracer extraction was in patients with ICM (4.5 ± 0.5%), and the lowest in patients with ICP (3.2 ± 0.4); in DCM patients this index had an intermediate value (3.6 ± 0.1%).

Intravital study of myocardial bioenergy showed an increase in cardiomyocyte mitochondrial respiration rate (Δ%) in both patients with DCM and ICM (fig. 1). The amplitude of variation in DCM patients with HF and NYHA class III-IV was obviously lower than that obtained in HF patients and NYHA class I-II.

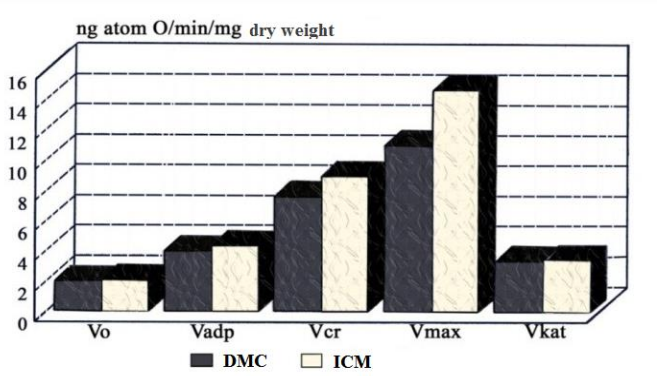

Fig. 1. Indices of cardiomyocyte mitochondrial respiration in patients with DCM and ICM

Optical microscopy identified cells with vesicular content, characteristic for apoptosis. Apoptotic corpuscles, along with other damaged structures, were detected in the sarcoplasm of isolated cardiomyocytes.

Throughout the study group, by *electron microscopy* were detected destroyed cardiomyocytes with large areas of abnormal orientation and myofibrillar lysis, mitochondrial destruction, sarcoplasmic reticulum vacuolization, sometimes disruption of intercalated disc-like cell contacts. In all cases, cardiomyocytes undergoing apoptosis were found.

TUNEL method (terminal deoxynucleotidyl transferase dUTP nick end labeling) revealed the presence of immunoreactive nuclei in all studied cases. The apoptotic index (AI) ranged from 1% to 12.86 ± 1.62%. In patients with DCM and ICM, IA was identical, namely 2.19 ± 0.82% and 2.17 ± 0.82%, respectively.

Using *immunoblot method* we assessed the levels of annexin V and VI in LV cardiomyocyte membrane. A significant increase in annexin levels was obtained in DCM patients compared to control group: 122 ± 5% ($p < 0.05$) and 119 ± 5% ($p < 0.05$) for annexin V and VI, respectively.

Expression of myosin light chain kinase (MLCK) and related protein kinase (KRP) was increased by 70% in DCM and by 52% in ICM.

DISCUSSION

The macroscopic analysis of the hearts performed during the autopsy revealed a significant increase, of up to 5 times, in heart mass in patients with DCM. This obvious hypertrophy of the myocardium is

one of the specific morphological characteristics of this disease. It should be noted that ventricular free walls and IVS thickness at different levels was within normal range, and no relationship could be established between walls thickness, ventricular volumes and heart mass. Based on this finding, we consider that ventricular walls thickness, which in daily practice is determined by transthoracic echocardiography, should not be considered a criterion for the presence or absence of myocardial hypertrophy in DCM patients. Relevant in DCM seems to be the biochemical aspects of the cardiomyocyte hypertrophy, namely the changes in cells protein composition. Thus, in the myocardium of the investigated patients we found hypertrophy of a significant part of cardiomyocytes, with partial return to the fetal program of protein expression. The increased MLCK and KRP expression may partially be responsible for the non-adaptive nature of cardiomyocyte hypertrophy. Despite the increase in size of functional fibers, the efficacy of contraction proves to be low (6).

In patients with DCM, morphological data reveal diffuse, microfocal or diffuse microfocal sclerosis. In more than 25% cases were detected foci of replacement myocardial sclerosis with intramural vessel sclerosis phenomena, which can prove that the onset of the disease was with myocarditis accompanied by proliferative and necrotizing vasculitis. The above presented data show not only the lack of specificity, but also the essential heterogeneity of myocardial changes in patients with DCM. Most likely, they indicate different stages of the pathological process and/or the primary influence of various etiological factors on the heart (7).

Central hemodynamic data showed moderate pulmonary hypertension in patients with DCM and ICM, which can be explained by the simultaneous involvement of both left and right cardiac cavities. As a result, the LVEF is lowered to a greater extent. Severe pulmonary hypertension may be determined by both severe LV systolic dysfunction and moderate RV changes, as well as by the development of sclerotic changes in small pulmonary vessels, as a result of long-term disease progression. In patients with DCM and ICM, which usually have a relatively short duration of disease, pulmonary hypertension fails to develop.

The segmental anomalies of LV contractility are most probably due to focal sclerosis and/or to conduction abnormalities in bundle of His, particularly at the level of the ventricular myocardium. Heart rhythm and conduction abnormalities were equally frequent in patients with DCM and ICM. In both groups, supraventricular and ventricular arrhythmias, as well as atrioventricular and intraventricular conduction abnormalities occurred as frequently. The need for an in-depth knowledge of the proarrhythmic substrate lies in the necessity of optimal control of the most common rhythm disorder associated with DCM, namely atrial fibrillation. The structural and functional changes that it determines in the atria (8) trigger a cascade of maladaptive events at the ventricular level, with negative consequences on the telediastolic pressure, parietal tension and LV ejection fraction. Long-term persisting arrhythmia and the treatment associated adverse effects have major impact on the patient's prognosis and quality of life (9).

The coronarography data clearly demonstrated the morphological and functional changes in the myocardial vasculari-

zation of DCM patients, thus confirming the presence of chronic myocardial hypoxia. It must be taken into account that 70% of the energy required from the myocardial cell is the result of aerobic oxidation of fatty acids, and prolonged ischemia results in reduction of this process, intensification of anaerobic glycolysis and accumulation of no oxidized fatty acids (10).There is increasing evidence that cardiac lipid accumulation worsens heart function and leads to structural myocardial damage, including cardiac fibrosis, myocyte apoptosis, and reduced contractility (11), which is often linked to mitochondrial dysfunction. This persistent deficiency of cardiomyocyte oxygenation and its crucial involvement in the primary and/or secondary injury of the cardiomyocytes is strongly supported by our intravital study of myocardial bioenergy. For this highly specialized evaluation, we used the permeabilized fiber method, a high-fidelity technique, of great utility in clinical trials in patients with different pathological conditions (12). Our data revealed serious abnormalities in the biosynthesis chains of various isoenzymes in DCM patients, but similar to those recorded in ICM patients.

A major breakthrough in understanding the complex mechanisms that leads to DCM was achieved by assessing apoptosis in myocardial cells. By combining electron and optical microscopy with the TUNEL test, a highly specialized immunohistochemical method, we proved the presence of immunoreactive nuclei in all myocardial biopsies from DCM patients. Based on this undeniable evidence, we affirm without hesitation that myocardial wall thinning, as well as the reduction in cardiomyocyte count occurred in the absence of collagen accumulation in the myocardium. This phenomenon indicates a low coefficient of necrotic cell death and allows us to confirm previous studies (13), who states that apoptosis is the primary factor responsible for the pronounced dilation of cardiac cavities in patients with DCM.

Immunoblotting method allowed us to highlight the increased levels and the particular disposition of annexin V and VI in myocardium of DCM patients. In healthy myocardium, at subcellular level, annexin V and VI are present in the sarcolemma, intercalated discs and T-tubules, connected to the terminal cisternae of the sarcoplasmic reticulum where excitation-contraction coupling takes place. In DCM patients, we found a particular localization of annexin V in the myocardium, especially in the interstice, between myocyte clusters, at sites corresponding to fibrous tissue. This abnormality, together with annexin V ability to bind at the extracellular matrix proteins (14), are likely to contribute to the development of “reactive” interstitial fibrosis and to the structural reorganization of ventricular myocardium. These are the clearest features of heart failure.

Although the changes we found are not specific for DCM and rather confirm the common characteristics of advanced stages of the disease, they elucidate the incidence and the pathophysiological substrate of heart rhythm disorders in patients with DCM and ICM. All the morphological, morphometric and bioenergetic abnormalities that we documented, along with the impairment in the regional myocardial contractility and changes in the intracardiac hemodynamic parameters strongly support the fact that DCM has multiple and incompletely elucidated mechanisms, that lead to a unique clinical aspect, regardless of etiology.

CONCLUSIONS

The results of our research states that the identified changes are not related to the etiopathogenic characteristics of DCM. However, they reflect a clearly contoured syndrome, characterized by morphological, morphometric and bioenergetic myocardic indices, intracardiac hemodynamic parameters and, regional and global myocardial contractile dysfunction. These data confirm the common character of structural and functional changes of the myocardium in advanced stages of the disease. The concept is supported by the similarity of incidence and pattern of heart rhythm disorders and also by abnormalities of myofibrillar proteins in patients with DCM, ICM and ICMP. Certainly, more studies are necessary to correlate accurately the parietal kinetic parameters with intracellular metabolic processes.

ACUTE TOXICITY OF ANGIOTENSIN CONVERTING ENZYME. INTERNAL MEDICINE AND TOXICOLOGY CLINIC OF IASI EMERGENY HOSPITAL EXPERIENCE (Abstract): Regarding angiotensin-converting enzyme inhibitors (ACEI) poisoning, only few data are available in the last decade literature. In the previous couple of years especially isolated case reports were published. **Material and method**: We analyzed retrospectively all the patients with acute ACEI poisoning admitted in Iaşi Internal Medicine and Toxicology Clinic between 2004 and 2009. **Results**: 17 cases of poisoning were recorded (enalaprilum-9 cases, captoprilum-3 cases, perindoprilum-3 cases, lisinoprilum-2 cases). All the poisonings were intentional. A favorable outcome was consistently observed, and were recorded no sequelae or death in this study. The main complain was hypotension, required fluid administration, only one case with 500 mg enalaprilum and severe hypotension required injection of vasopressive amines. No abnormal renal function and no angioedema were noted. **Key words**: ANGIOTENSIN-CONVERTING ENZYME INHIBITORS TOXICITY, ANGIOTENSIN-CONVERTING ENZYME INHIBITORS POISONING, HYPOTENSION

LUNG CANCER IN PATIENTS WITH PULMONARY TUBERCULOSIS: EPIDEMIOLOGICAL AND CLINICAL FEATURES

LUNG CANCER IN PATIENTS WITH PULMONARY TUBERCULOSIS: EPIDEMIOLOGICAL AND CLINICAL FEATURES (Abstract) **Aim**: To describe the clinical and epidemiological features of patients who developed simultaneously lung cancer (LC) and pulmonary tuberculosis (PTB). **Material and methods**: Retrospective study of the medical records of patients diagnosed with LC and PTB at the Constanta Pneumophtysiology Hospital between January 1, 2014 and December 31, 2018. Demographic data (age, gender, occupation), risk factors, clinical status, histopathological type of LC, stage at diagnosis, LC therapy, and laboratory results (sputum smear or bronchoalveolar lavage microscopy, culture, susceptibility testing for *Mycobacterium tuberculosis*) were collected. All hospitalized patients were evaluated. **Results**: Of the 559 LC patients, we identified 54 patients that had active TB at the time of LC diagnosis, mean age 57.27 ± 11.26 years, 37 (67.27%) men and 18 (32.73%) women. Most patients were smokers or former smokers (90.4%), diagnosed at an advanced stage (90.7% stage III and IV), and adenocarcinoma was the most frequent histologic type (40.7%). Positive smear microscopy was recorded in 24 (44.4%) patients, and 7 patients reported a history of TB contact. Thirty-eight (70.3%) of patients were new TB cases, 16 (29.6%) were relapses, and one patient was diagnosed with multidrug resistant (MDR) TB. **Conclusions**: LC patients with concurrent pulmonary TB were mostly males, smokers, with advanced LC, adenocarcinoma being the most common histologic type, with almost half of the cases, with positive smear microscopy.
Keywords: LUNG CANCER, PULMONARY TUBERCULOSIS, COMORBIDITY.

At the end of the 20th century, lung cancer (LC) became one of the leading causes of death worldwide. LC is a tumor of extreme severity, less than 1/3 of cases being diagnosed at a localized stage (1). Smoking is the most common risk factors not only for LC (2), but also for other pulmonary or extrapulmonary diseases (3-5). Involuntary inhalation of cigarette smoke and the use of electronic cigarettes are as harmful as active smoking (6, 7). In addition to smoking, there are many other risk factors associated with LC, such as environmental exposure to noxious particles or gases, predisposing conditions (pulmonary fibrosis, TB scars) or a family or personal history of cancer (1, 8).

PTB is a major health problem globally, Romania reporting the highest incidence

(72/100,000 population) in the European Union (9). In Romania, every year, more than 1,000 people die of and other 16,000 are newly diagnosed with PTB. The most common risk factors for PTB are various immunosuppressive conditions, malnutrition, indoor air pollution, smoking and alcohol use, and low socioeconomic status (10, 11).

Coexistence of LC and PTB remains a clinical problem that presents a real challenge for the management of both diseases. There are patients diagnosed with LC who develop active TB disease, mainly by reactivation of a latent PTB due to prolonged immunosuppression caused by chemotherapy, radiation therapy or their overall poor health status and malnutrition. On the other hand, chronic inflammation, the major pathogenic process in TB, appears to be the basis for the future development of LC (12).

The aim of the study was to describe the clinical and epidemiological characteristics of patients who developed simultaneously LC and PTB.

MATERIAL AND METHODS

A retrospective study of the medical records of patients diagnosed with LC and PTB at the Constanta Pneumophtysiology Hospital between January 1st , 2014 and December 31st, 2018, was conducted. There were assessed all LC patient files and demographic data (age, gender, occupation), risk factors, clinical status, histopathological type of LC, stage at diagnosis, LC therapy, and laboratory results (sputum smear or bronchoalveolar lavage microscopy, culture, susceptibility testing of *Mycobacterium tuberculosis*) were collected. The diagnosis of PTB was based on the national consensus criteria (13): positive Ziehl-Neelsen staining for acid fast bacilli (AFB); positive culture for *Mycobacterium*; or epidemiological, clinical, and radiological features consistent with PTB, associated with a favorable response to anti-tuberculosis treatment. LC diagnosis was based on cytology and/or anatomopathological findings.

This study was approved by the Ethics Committee of the Constanta Pneumophtysiology Hospital. Patient informed consent was not needed because the study was retrospective.

Statistical analysis was performed using the *Statistical Package for the Social Sciences version 18.0* (SPSS Inc., Chicago, IL, USA). A descriptive analysis of the study variables was carried out. Qualitative data are expressed as n (%), and quantitative data as mean ± SD.

RESULTS

There were assessed 559 files of patients diagnosed with LC during the study period, of which 54 (9.6%) patients with active TB disease were included in the study. Yearly and gender distribution of the cases diagnosed and hospitalized for LC and concomitant PTB during the study period is presented in figure 1.

Patients' data including age, sex, smoking and clinical status, histopathological type of LC, stage at diagnosis, and LC therapy are shown in first table. The study group consisted of 54 patients diagnosed with LC and PTB, of which 37 (68.51%) men and 17 (31.38%) women. Mean age was 57.27 ± 11.26 years (55.86 ± 12.43 years in men, and 60.65 ± 11.34 years in women). Most of patients (n=49/54; 90.74%) were smokers or ex-smokers, and more than half of them (n=29; 53.7%) were living in urban areas. Six (11.11%) patients had a history of respiratory toxicant exposures. The most common histopathological type was adenocarcinoma (n=22; 40.74%), followed by squamous cell carcinoma (n=19; 35.18%), while

small cell carcinoma was diagnosed in only 5 (9.25%) patients.

Most patients (n=49; 90.73%) were diagnosed in advanced stages (III B, C and IV). Of the 5 patients diagnosed in operable stages (I, II, IIIA), only 3 underwent surgery, the other two presenting serious cardiovascular comorbidities that prevented the surgical procedures. 36 patients underwent chemotherapy, of which 8 patients had concurrent or sequential radiation therapy. One patient benefited from all 3 therapeutic possibilities, while 16 patients received only symptomatic treatments, either because of severe comorbidities or because of refusal of therapy.

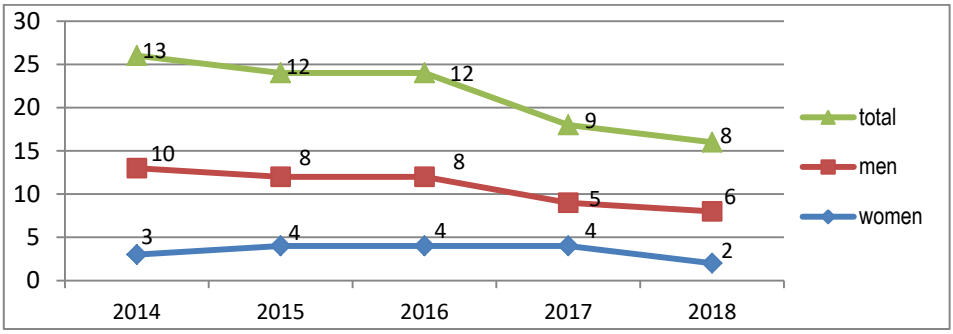

Fig. 1. Number of LC and PTB patients diagnosed during the study period

TABLE I

Characteristics of the patients diagnosed with LC and PTB

Variables	Number	Percent (%)
Age, years, mean ± SD	57.27±11.26	
Male gender	37	68.51 %
Smoker or former smoker	49	90.74 %
Urban residence	29	53.70 %
History of respiratory toxicant exposure	6	11.11 %
Performance status ECOG ≤ 1 ECOG ≥ 2	 31 23	 57.4 % 42.59 %
Pathological type Adenocarcinoma Squamous cell carcinoma NSCLC, undetermined Small cell carcinoma	 22 19 8 5	 40.74 % 35.18 % 14.81 % 9.25 %
Stage I and II III A III B, C IV	 1 4 16 33	 1.8 % 7.4 % 29.62 % 61.11 %
Treatment Chemotherapy Radiotherapy Surgery	 36 8 3	 66.66 % 14.81 % 5.55 %

The PTB diagnosis was made using the following methods: sputum smear microscopy in 24 (44.44%) patients; sputum culture in 44 (81.48%); bronchoalveolar lavage (BAL) microscopy in 2 (3.7%); BAL culture in 4 (7.4%); PCR positivity for M. tuberculosis in BAL samples in 6 (11.11%); and clinical and radiological findings consistent with tuberculosis in 8 (14.81%) patients (tab. II). Thirty-eight patients were new TB cases, while 16 were relapses. One patient was diagnosed with multidrug resistant TB. The treatment of PTP was completed by 40 patients, 5 patients died and for 9 patients the data regarding treatment outcome were unavailable.

TABLE II
Characteristics of PTB

PTB characteristics	Number	Percent (%)
History of TB contact	7	12.96
Positive sputum smear microscopy	24	44.44
Positive BAL microscopy	2	3.7

DISCUSSION

The present study describes the characteristics of 54 patients simultaneously diagnosed with PTB and LC over a 5-year period. This period was characterized by a decrease in the annual number of patients (13 patients in 2014 versus 8 patients in 2018). This descending trend can be explained by the decrease in TB incidence at country level (9).

The association between PTB and LC has been studied for years (14-20). These two diseases can mimic the clinical and radiological features of each other, therefore the diagnosis may be delayed. There are various hypotheses regarding a plausible biological mechanism explaining the association between LC and PTB. One of these would be that chronic inflammation associated with prolonged infections can contribute to carcinogenesis (15). Activated neutrophils produce reactive oxygen or nitrogen species that can bind to the DNA, inducing genetic damage and neoplastic transformation (16). In patients with chronic infections, such as PTB, it has been demonstrated that histidine triad gene alterations may be involved in lung carcinogenesis, along with increased cell proliferation and angiogenesis during tissue repair (15, 16).

In conditions of impaired local immunity due to lung carcinoma or various administered therapies, primary mycobacterial infection, reactivation of a latent TB, or new exogenous infection may cause TB disease (17).

In the present study, of the 559 patients diagnosed with LC, 54 (9.6%) were found to have simultaneously PTB. In a cross-

sectional study (18) involving 24 patients diagnosed with tuberculosis and LC, the diagnoses of PTB and LC occurred simultaneously in 10 patients, whereas PTB was diagnosed prior to LC in 14. The high number of patients diagnosed concomitantly with LC and PTB in our study can be explained by the fact that TB is highly endemic in our country, Constanta county being one of the highest endemic areas.

In this study the most common histopathological type of LC was adenocarcinoma (40.74% of cases), similar to those reported in previous studies (18,19). A meta-analysis (20) of 37 case-control studies and 4 cohort studies showed a significant association between tuberculosis and adenocarcinoma (RR = 1.6; 95% CI = 1.2-2.1), but not with squamous cell carcinoma or small cell carcinoma.

Almost 91% of patients included in this study were smokers or former smokers, fact that can lead to the idea that these two diseases share the same risk factor, tobacco smoking. Despite the well-known effect of tobacco as a carcinogen, the association between PTB and LC persists even in never smoking individuals (RR=1.8, 95% CI=1.4-2.2) (20). Similar with previously reported data, approximately one of 10 patients were exposed to respiratory toxicants, thus demonstrating the negative impact of occupational exposure on respiratory system (21).

Approximately 60% of our patients presented distant metastases at the time of LC diagnosis and almost half of them with positive sputum smear or BAL microscopy showing an advanced stage of both diseases (22). This can be explained by the fact that these two diseases have common symptoms that can cause a delay in their diagnosis. Prevention measures, early-stage disease diagnosis with the use of "red-flags" during anamnesis in the general practicians' offices and more often updates of the protocols are needed (23).

CONCLUSIONS

The present study showed that patients with lung cancer and concurrent pulmonary TB were mostly males, smokers, with advanced stage of LC. Adenocarcinoma was the most common histologic type, almost a half of the cases had positive smear microscopy.

THE PROGNOSTIC IMPACT OF THE NEUTROPHIL-TO-LYMPHOCYTE RATIO IN PATIENTS WITH ADVANCED NON-SMALL-CELL LUNG CANCER WITH PULMONARY COMORBIDITIES (Abstract): **Aim:** This study assesses the prognostic role of the neutrophil-to-lymphocyte ratio (NLR) and other clinical parameters in patients with advanced non-small-cell lung cancer (NSCLC) who also suffer from pulmonary comorbidities. **Material and methods:** This single-center retrospective research was conducted during January 2015 – December 2018 on patients with the above-mentioned diagnosis. The statistical analysis was carried out with SPSS version 25.0 and focused on evaluating the independent effects of NLR and other parameters by means of univariate and multivariate Cox regression analyses. **Results:** Regarding progression-free survival (PFS), the results of the multivariate analysis did not indicate NLR as a prognostic factor (HR: 1.34; 95% CI: 0.85-2.11; p=0.2), unlike the ECOG performance status (HR: 1.71; 95% CI: 1.06-2.77; p=0,02). In terms of overall survival (OS), NLR was an independent negative prognostic factor (HR: 1.8; 95% CI: 1.21-2.69; p=0.004), and so was smoking (HR 1.97; 95% CI: 1.23-3.15; p=0.005). **Conclusions:** While we did not find NLR to be an independent prognostic factor for PFS in patients with NSCLC and pulmonary comorbidities, it proved to be a negative prognostic factor for OS in these cases. **Keywords:** ADVANCED NSCLC, PULMONARY COMORBIDITIES, NLR, PROGNOSIS.

Worldwide, lung cancer is currently both the most common type of neoplasm as well as the deadliest (1). Up to 80% of cases feature non-small-cell lung cancers (NSCLC). Over the course of the last ten years, survival rates have improved for patients in all stages of lung cancer, with particularly good outcomes in early stages significantly alleviated by multimodal therapies (2, 3). TNM staging has proven useful in classifying lung cancer cases based on severity and one of the most important practical implications is in predicting outcome. However, it is limited in that it does not meet all the necessary criteria for being a complete prognostic tool. Nevertheless, most studies employ TNM in order to stratify and assess patient outcomes (2). The current situation raise an unmet need for more cost-effective biomarkers capable of providing reliable prognostic information which may then guide therapeutic decision-

making (4). Numerous studies have so far demonstrated the prognostic role of various clinical, biological and genetic factors in advanced and metastatic lung cancer, but none that we could identify has yet researched this in a population of Romanian patients and specifically on a cohort with pulmonary comorbidities. Our study aims to fill this gap and assess the prognostic role of NLR and other variables in patients with non-small-cell lung cancer and pulmonary comorbidities

MATERIAL AND METHODS

Patient selection

Upon approval by the Ethics Committee of the Regional Institute of Oncology Iași (RIO) and the Ethics Committee of the "Grigore T. Popa" University of Medicine and Pharmacy Iași, we proceeded to conduct a retrospective study on patients previously diagnosed with locally-advanced NSCLC ineligible for surgical/radiotherapy treatment or already in the metastatic stage. The patients to be taken into consideration had undergone chemotherapy and targeted molecular therapies at RIO in Iași over the course of 3 years (2015-2018). The data was retrospectively collected using the Hippocrates information system with which RIO manages all the patient data. The selection process resulted in a database including clinical, biological, histopathological and molecular parameters for each case. Information regarding investigations, therapeutic decisions, and patient outcomes were also considered. The studied variables were: age, gender, ECOG performance status, smoking and number of packages per year, comorbidities, pathological diagnosis, oncogenic mutations of the epidermal growth factor receptor (EGFR) gene, TNM staging, location of the primary tumor, location of the metastases, undergone treatment, first-line chemotherapy, neutrophil-to-lymphocyte ratio (NLR), first-line targeted molecular therapies, toxic reactions to treatment, treatment outcomes, progression-free survival (PFS) and overall survival (OS).

The inclusion criteria were:

- age > 18 years old;
- histology of squamous cell carcinoma or adenocarcinoma;
- locally advanced either ineligible for surgery/radiotherapy or in metastatic stage;
- no prior oncologic treatment for lung cancer;
- treatment carried out at RIO Iași;
- diagnosis of pulmonary comorbidities.

The exclusion criteria were:

- other histologies than typical of squamous cell carcinoma and adenocarcinoma;
- history of cancer;
- severe cardiovascular comorbidities – recent myocardial infarction, severe angina pectoris, stroke and severe peripheral arterial disease.

The tumor staging was established using the 7th edition of the staging system developed by the American Joint Committee on Cancer.

Statistical analysis

The Chi-square test was used to compare the clinical characteristics of the groups with elevated and low NLR. Overall survival was defined as the length of time between the lung cancer diagnosis date and the time of death due to cancer, and the Kaplan-Meier method was used to estimate it. The univariate analysis was performed using the log-rank test, also helpful in establishing the prognostic differences between the groups. Cox regression was used to develop multivariate models. Hazard ratios and 95% confidence intervals were computed, and the default threshold for statistical significance was set at 0.5. All the patient data collected over a peri-

od of 3 years from the time of diagnosis (or less in case of death) was considered as explained. The characteristics of the patients are summarized in first table.

RESULTS

Patient characteristics

During January 2015 – December 2018, a total of 488 new cases of NSCLC were recorded as being treated at RIO. Of them, 109 patients met the criteria for inclusion in this study and did not feature any of the exclusion criteria. These patients underwent first-line chemotherapy or targeted molecular therapies if manifesting oncogenic mutations of the EGFR.

TABLE I

Clinical characteristics of the patients

No. of cases		109 (100%)
Median age (years)		63
Gender	Male	88 (80.7%)
	Female	21 (19.3%)
ECOG	0	2 (1.8%)
	1	67 (61.5%)
	2	40 (36.7%)
Smoking status	Smokers	83 (76.1%)
	Non-smokers	26 (23.9%)
Histology	Adenocarcinoma	58 (53.2 %)
	Squamous cell carcinoma	51 (46.8 %)
Stage	IIIA	8 (7.3 %)
	IIIB	18 (16.5 %)
	IIIC	9 (8.3 %)
	IVA	39 (35.7 %)
	IVB	35 (32.1 %)
Metastases	Absent	33 (30.2 %)
	Pulmonary	56 (51.3 %)
	Hepatic	9 (8.2 %)
	Osseous	13 (11.9 %)
	Cerebral	2 (1.8 %)
	Adrenal	10 (9.1 %)
	Other locations	0 (0 %)
1st line chemotherapy	Cisplatin Gemcitabine	48 (44%)
	Carboplatin Gemcitabine	30 (27.5%)
	Carboplatin Paclitaxel	12 (10.1%)
	Other protocols	19 (17.5%)
Pulmonary comorbidities	COPD	73 (69.6%)
	Pulmonary fibrosis	6 (5.5%)
	Asthma	6 (5.5%)
	TB history	2 (1.8%)
	Other comorbidities	19 (17.6)

The clinical characteristics of this patient population are summarized in Table I. In all, data on 109 patients treated during January 2015 – December 2018 were eligible for analysis. The median age of the patients was 63. Regarding gender, 88 patients were men (80.7%) and 21 were women (19.3%). A majority of 83 patients were smokers (76.1%). Adenocarcinoma-type histology was present in 53.2% of the cases, and squamous cell carcinoma in the other 46.8%. There were 35 cases diagnosed as stage III (32.1%) and 74 as stage IV (67.8%). The most common secondary lesions were pulmonary (51.3%). The most frequently associated chronic pulmonary pathology was chronic obstructive pulmonary disease (COPD), in 66.9% of cases), while a prior history of pulmonary fibrosis was rare (only 5.5%). The most commonly employed first-line chemotherapy protocol Cisplatin Gemcitabine (44%) and Carboplatin Gemcitabine (27.5%). Considering that EGFR mutations were also present in some of the patients, first-line Erlotinib was used in 3 cases and Afatinib in one other. For the studied population, the median PFS was of 7.7 months and the median OS was of 12.6 months.

Inflammation markers based on biological sampling

The median values of the levels of neutrophils and lymphocytes were 8.7 x 10^9/l and 2.9 x 10^9/l, respectively. The NLR was defined as the number of neutrophils divided by the number of lymphocytes, thus resulting in a median NLR value of 3.32 for the entire cohort (with individual values ranging from 0.2 to 16.3). The cases were further grouped in two: patients with elevated NLR (≥ 3) and those with low NLR (< 3).

NLR-related parameters

The clinical and pathological characteristics correlated with NLR values are summarized in second table. There were no significant associations found between NLR and age, gender, smoking status, the histopathological type of the TNM clinical staging. There were significantly more ECOG 1 and ECOG 2 patients in the group with NLR ≥ 3 compared to the NLR<3 group (p=0.02).

TABLE II

Correlations between clinical characteristics and NLR

	NLR

Absent	41 (89.1)	53 (84.1)	
Present	5 (10.9)	10 (15.9)	

NLR and PFS

The median PFS was of 7.8 months (ranging between 1 and 47.5 months). At 1-year PFS was 16% of the NSCLC patients with pulmonary comorbidities and NLR ≥ 3, as well as in 32.5% of the patients with NLR < 3. The univariate analysis was conducted in order to establish any existing correlations between PFS and various parameters. Age (p=0.89), gender (p=0.85), smoking (p=0.3), the histopathological type (p=0.2), the clinical staging (p=0.9), the location of the primary tumor (p=0.9) and the presence of EGFR mutation (p=0.58) did not significantly associate with PFS, unlike the ECOG performance status (p=0.005) and NLR (p=0.03), as summarized in Table III. Also, the patients from the elevated NLR group had shorter PFS than those with low NLR (6.1 months versus 9.5 months – see fig. 1). However, the multivariate analysis did not highlight a significant association between NLR and PFS (HR: 1.34; 95% CI: 0.85-2.11; p=0.2). The ECOG performance status proved to be an independent prognostic factor for PFS (HR: 1.71; 95% CI: 1.06-2.77; p=0.02) (tab. III). The median PFS of the patients with ECOG 0 was 12 months, while for patients with ECOG 1 it was 8.5 months and for those with ECOG 2, it was only 4.6 months (fig. 2).

TABLE III

Univariate and multivariate analysis of PFS for patients with advanced NSCLC and pulmonary comorbidities

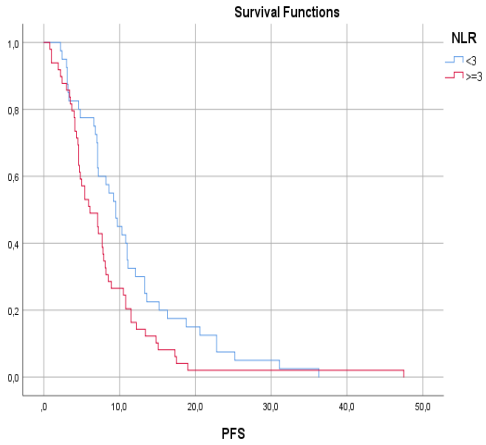

Fig. 1. PFS and NLR for patients with advanced NSCLC and pulmonary comorbidities

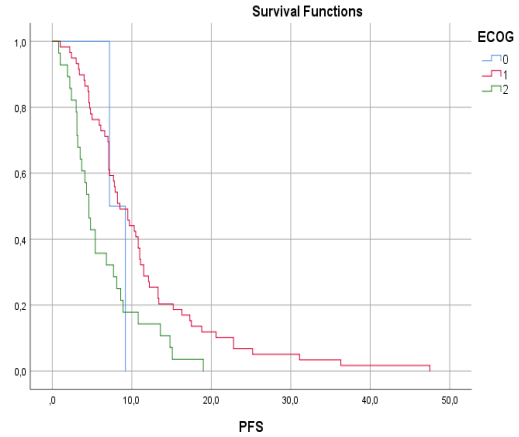

Fig. 2. PFS and ECOG for patients with advanced NSCLC and pulmonary comorbidities

NLR and OS

The median overall survival was of 15.4 months (ranging between 10.1 and 21.8 months). The 1-year OS rate was significantly lower in patients with elevated NLR compared to the group with low NLR (40% vs 70%). According to the univariate analysis, the variables correlated with poor OS were smoking (p=0.01) and elevated NLR (p=0.01). The multivariate analysis pointed elevated NLR as an independent prognostic factor for short OS (HR: 1.8; 95% CI: 1.21-2.69; p=0.004). Also, smoking status was a negative prognostic factor (HR 1.97; 95% CI: 1.23-3.15; p=0.005) (tab. IV). The median OS values were lower in the case of patients with advanced NSCLC and pulmonary comorbidities who also had elevated NLR than those with low NLR (10.5 months vs 15.8 months, p=0.01) (fig. 3).

TABLE IV

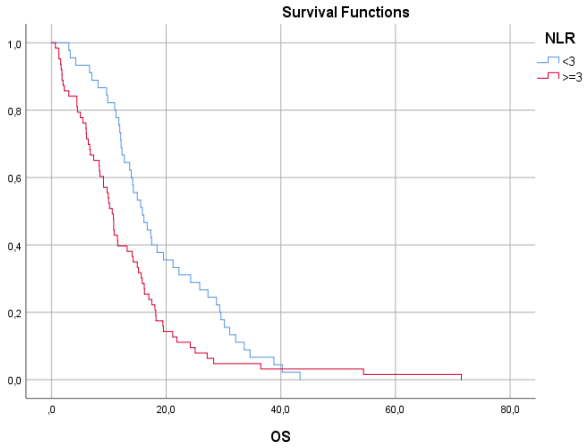

Fig. 3. OS and NLR in patients with advanced NSCLC and pulmonary comorbidities

DISCUSSION

NLR is the ratio between neutrophils and lymphocytes. This ratio influences the prognosis for cancer patients, but the underlying mechanism is unclear. Several hypotheses have been raised. For one, neutrophils seem to play several protumoral roles. Those from the tumor stroma exert protumor genic effects by inhibiting apoptosis, promoting angiogenesis and stimulating the formation of metastases, creating an inflammatory microenvironment conductive to malignant growth (5). Also, lymphocytes are essential in immunosurveillance and tumor suppression (6). CD41 helper T cells and CD81 cytotoxic T cells take part in immunosurveillance. Increased densities of CD41 helper T cells and CD81 cytotoxic T cells in tumor stroma are considered favorable independent prognostic factors in patients with NSCLC (7, 8). Moreover, lymphocytes engage in antitumoral activities which may cause cellular death and may inhibit the migration as well as the growth of tumor cells. In fact, they are the main inflammatory agents that inhibit the proliferation of cancer cells. Since an elevated NLR points to a large number of neutrophils and/or a small number of lymphocytes, this may explain why it is typically associated with an unfavorable prognosis in cancer patients (4).

According to our research, the NLR before starting the treatment of the studied patients represented a negative prognostic factor for OS (HR: 1.8; 95% CI: 1.21-2.69; p=0.004), but not for PFS (HR: 1.34; 95% CI: 0.85-2.11; p=0.2). In patients with pulmonary comorbidities, the median OS was 5.3 months shorter in patients with NLR < 3 compared to those with NLR ≥ 3.

In other clinical trials, elevated NLR has been linked to poor survival in patients with gastrointestinal cancers, pancreatic cancer, breast cancer, bladder cancer and other types of cancers. A recent meta-analysis of studies conducted on a total of 40 599 patients with solid tumors also showed that NLR > 4 was associated with a substantial increase in mortality risk. However, the cutoff value and the prognostic effect of NLR remain controversial (9, 10). Liu *et al.* assessed 934 patients with advanced lung cancer and demonstrated that

NLR is correlated independently with a favorable prognosis (11). In another study coordinated by Guo, low values of NLR were associated with increased OS in patients with advanced NSCLC who were treated with first-line platinum-based chemotherapy. Thus, NLR was demonstrated as an independent predictor for survival (12). Yu *et al.* conducted a meta-analysis on data from 7,219 patients and showed that elevated NLR predicted reduced OS (HR: 1.46l 95% CI: 1.30-1.64) as well as reduced PFS (HR: 1.42; 95% CI: 1.15-1.75) (13). Scilla's research confirmed the hypothesis that an elevated baseline NLR was associated with reduced OS in patients with advanced NSCLC who underwent chemotherapy (14). Building on the latest progress in the field of immunotherapy for lung cancer, a recent study found that elevated NLR can be linked to poorer prognosis ($p < 0.001$) in patients with metastatic NSCLC undergoing treatment with nivolumab. Accessibility to inflammation biomarkers could, in the future, make this a reliable predictive biomarker for immunotherapy in NSCLC (15).

The research hereby presented features several limitations. Mainly, this is a retrospective study conducted in a single center and on a relatively small number of patients. Also, despite our best attempts to compile the database using strictly managed inclusion and exclusion criteria, the results may still be influenced by uncontrolled selection biases.

CONCLUSIONS

Given the multitude of preclinical and clinical data reported in the literature, we believe there are multiple studies in support of NLR as a prognostic factor in stage III and stage IV NSCLC. Our study does more than corroborate by further enhancing the understanding that elevated NLR works as a negative prognostic factor in patients with pulmonary comorbidities. Also, we completed the existent literature with a population from Romania offering data about clinical, pathological and prognostic in patients with advanced NSCLC and pulmonary comorbidities.

PEDIATRIC AND ADOLESCENT ONCOFERTILITY - S.O.S .- FUTURE IS HERE!

Oncofertility is the multidisciplinary approach of oncologists and reproductive fertility specialists working together to achieve the goals of patients with cancer. The treatments for cancer disease like radiotherapy, chemotherapy and surgery or maybe combined therapy with the above methods may lead to premature ovarian insufficiency (POI) or substantial male germ cell loss. Therefore, reproductive medicine experts strongly suggest that all young patients diagnosed with a malignant tumor should immediately undergo a consultation with suggestions for fertility and endocrine function protection and preservation- methods such as sparing surgery, cryopreservation and so on. In this review authors discuss about the background knowledge, methods, indications, pros and cons, and experimental and clinical applications of fertility preservation, and new strategies for future fertility conservation to help physicians, especially oncologist, pediatrician, hematologist, and surgeons-"multidisciplinary team", become aware of the concepts, methods, and importance of fertility and endocrine function protection. Although there are many reasons for fertility preservation in children and adolescents, cancer is currently the main indication for fertility preservation, and interest in this group of patients has led to development of the oncofertility focus (Zhao H, Jin L, Yufeng L, *et al.* Oncofertility: What can we do from bench to bedside? *Cancer Lett* 2019; 442: 148-160. doi: 10.1016/j.canlet.2018.10.023).

THE ANALYSIS OF THE RELATIONSHIP BETWEEN INFLAMMATION, DEPRESSION AND SUICIDAL BEHAVIOR

THE ANALYSIS OF THE RELATIONSHIP BETWEEN INFLAMMATION, DEPRESSION AND SUICIDAL BEHAVIOR (Abstract): Major Depressive Disorder is in direct connection with serotonin, noradrenaline, and dopamine but the exploration of the role that inflammation has in depression has drawn to new conclusions that come in completion of the etiopathogenesis of depression. **Material and methods:** We have made a retrospective study consisting of a statistical comparative analysis that targets the patients committed to the Vth Clinic of the "Socola" Institute of Psychiatry from Iasi, between 2010-2017, diagnosed with major depressive disorder. There have been analyzed: demographic data, the intensity of the depression measured on the Hamilton scale, VSH values, and the suicidal associated risk. **Results:** There is a cumulation of factors that can determine the bidirectional relationship between depression and inflammation. The mechanisms that are at the base of it are not fully known but for women with associated suicidal risk from 2010, the elevated values of HAMD were associated with the higher values of VSH, that means at least for women, that depression is associated with a higher degree of inflammation. **Conclusions:** From the statistical analysis of the studied groups, the average value of HAMD was relatively constant as well in men and women, without considerable variations over the seven years. The difference consists in a stronger association between the women with severe depression and a higher VSH, over men, whereas we can observe lower VSH values, but with tendencies towards the superior limit, that supports an association between depression with the inflammation status, especially in patients with suicidal risk. **Keywords:** DEPRESSION, INFLAMMATION, SUICIDAL BEHAVIOR, IMMUNE SYSTEM.

A major depressive disorder is one of the more frequent conditions in psychiatric pathology and one of the main reasons for mortality and morbidity at a global level. Among the main criteria of this diagnostic are sad mood, anhedonia, fatigability, low vitality levels, symptoms that need to persist for at least two weeks. From the physiological point of view, the patient is presented with sleep disorders manifested as insomnia, low appetite, waking mood inconsistency, low libido. Also, the patient may experience feelings of futility, low energy levels and low focusing throughout the day, low self-esteem, predominant obsessive ideas of an autolytic nature the affects the overall ability of relationship functioning in society and family (1, 2).

The role of the inflammation in the etiopathogenic of depression is of very high

interest withing the research upon this field. Kafka, in 1990, in a letter to Miena, described his experience with tuberculosis *"The mind is the sick one and the lung condition is nothing else but the externalization of the psyche"* (3).

Depression consists of a rich heterogeneity both etiopathogenic and clinical. From the etiopathogenic point of view - depression can be classified as exogenous, endogenic, primary, and secondary, seasonal, or not, reactive, neurotic or psychotic, serotonergic, nor-adrenalin, or of dopaminergic nature.

Serotonin (5-HT) is a neuro-mediator with a modulator purpose within the neuronal circuit. Serotonin is created from the amino-acid tryptophan and is at the base of forming melatonin. It does not break the hematoencephalic barrier and it is secreted also at the central and peripheral levels. Some of the serotonin functions are the adjustment of the sleep and awake states, temperature adjustment, metabolism, sexuality, affectivity, motivation, pain, and adjustment of the blood pressure (4). From the limbic system point of view, dopamine has an uninhibited role and stimulates impulsivity. The inhibiting effect of the serotonin on the dopaminergic receptors dials down impulsivity, in such a way that when a deficit of serotonin occurs, therefore an imbalance between dopamine and serotonin levels, the excess of dopamine produces an uninhibited and impulsive behavior. Depression with high suicidal risk and bulimia are associated with increased impulsivity, and in some cases, the impulsivity may increase the risk of suicidal attempts (5).

Noradrenaline (NA) is a neuro mediator that affects multiple circuits that originate in the ocus coeruleus, which represents the nucleus with the most connections from the central nervous system that responds to new stimuli to manage the individual attention. Hypoactivity of these types of neurons generates hypoprosexia and hyperactivity produces an excessive fluctuation in attention that can be found as a symptom in maniacal behavior and ADHD (6).

Dopamine (DA), is the primary neuro mediators of the central nervous system and is a pre-component of nor-adrenaline. Dopamine is produced by the middle hypothalamic nucleus and has a role in motility control and muscle movement. It also has an inhibitory effect on prolactin. It reduces the levels of insulin production by the pancreas. Dopamine also reduces the activation of the lymphocytes within the immune system and from the renal point of view it modules the elimination of sodium by increasing the volume of excreted urine. DA also affects the pineal gland, having a very important role in the adjustment of the circadian/nictemeral rhythm. The deficit of dopamine can lead to certain neurological disorders such as Parkinson's Disease. The excess of dopamine may cause psychotic disorders and schizophrenia (7).

The connection between the immune system and the brain was not established until 1985 when a group of scientists has brought scientific proof regarding the suppression of the immune response in depression. The study had as primary objective exploring the role of inflammation in depression and the connected inflammatory mechanisms involved. The study leads to 3 main conclusions: High levels of inflammatory markers are present in patients with major depressive disorder, in absence of somatic conditions; the coexistence of depression with inflammation, and high risk of depression in the treatment with a cytokine (8). Numerous inflammatory bi-

omarkers have been identified with high values within the patients with depression (9). It is a well-known fact that major depressive disorder involves immune suppression that is proved by a reduction if cytotoxicity of the natural killer cells and a lymphocyte proliferation as well as an activation of the immune response indicated by an increase of the inflammatory mediator levels (10).

The effects of the inflammation on the psychic state and behavior could be partially mediated by the metabolites of the kynurenine pathways by modulating the neuroinflammation and neurotransmission of the glutamate (11). At the same time, in patients with suicidal tendencies, the factors that contribute to the inflammatory modifications can be attributed to mechanisms such as autoimmune responses, neurotropic pathogens, stress, and traumatic cerebral lesions (12, 13). Exploring the inflammatory systems from the perspective of its contributions to the suicidal behavior could offer new therapeutical approaches such as potential biomarkers for identifying patients with a high risk. To achieve the objective of improvement of the mechanisms of identifying and treating suicidal patients, the origin of the mechanisms of the effects of the suicidal behavior must be carefully studied (14, 15).

The therapeutical alliance between doctor, patient, and family represents the first step in initializing the depression treatment and ensuring better compliance of the treated patient. This aspect is essential both with patients treated ambulatory and with hospitalized patients (16). For many depressive patients, the association between psychotropic medication and psychotherapy seems to be the best option. Because of the high frequency of this particular pathology within the psychiatric practice, new directions in research of optimization of treatment need to be implemented and we are talking here of the hypothesis of the inflammatory mechanisms in depression (17, 18).

MATERIAL AND METHODS

To evaluate the correlation between inflammation, the intensity of depression, somatic and psychiatric comorbidities associated, we have made a retrospective study consisting of a statistical comparative analysis that targets patients committed to the V clinic of the "Socola" Institute of Psychiatry from Iasi, between 2010-2017 diagnosed with major depressive disorder (tab. I). The following parameters have been analyzed: demographic data, the intensity of the depression measured on the Hamilton scale, VSH values, and the suicidal associated risk.

The groups of patients were selected by accessing the electronic archive of the "Socola" Institute of Psychiatry from Iasi, and by consulting their observation files. The patients have expressed their consent when they were initially committed and agreed with the use of their data for scientific purposes.

Data analysis

The statistic calculations were made in *MS Excel* and pursued the correlations between the intensity of the depression using the HAMD score and VSH value. At the same time, the linear regression function was used and the statistical analyses *ANOVA* to underline the presence of a significant p, the significative threshold is 0.05.

RESULTS

The analysis of the values, graphics, and percent followed the VSH increasing values, according to the age group standards: groups of women and men ages between 20-40 years old and 41-60 years old

with VSH < 20 and women and men > 61 years old with VSH < 30. The age groups represent the second classification criteria. For each patient, it has been registered the level of depression (according to the Hamilton Depression Rating Scale / HAMD) and the anxiety level (according to the Hamilton Anxiety Scale / HAMA), and the interval and average values have been presented for each age group because, in the moment of commitment, the depression level (HAMD) was considered severe.

TABLE I

The report for men/women committed between the years 2010 and 2017

Year	Total of patients	MEN	WOMEN
2010	198	105	93
2017	156	79	67

By analyzing the graphic from above, we can conclude that there were no major differences between the number of women and men committed in the year 2010, and also 2017, the percentage is 53% men over 47% women and 51% men over 49% women. The statistic differences are very small even though in 2010 the differences were not far superior, it can be noted a tendency of equalization between the number of cases in men and women altogether.

If we are considering the environment whereas the patients were from, in the years 2010 and 2017, the stats are very similar with 54% from the urban environment over 46% from the rural environment. The environment does not represent a precise variable so it can influence this actual study, considering the population migration from rural to urban, most of them being probably classified in the electronic archive as coming from a rural environment.

Regarding the distribution on age groups, it has been noted that in the year 2010 as well as in 2017 the fact that the majority of patients are part of the age group 41-60 years old, with a significant decrease of the number of depression cases in the younger age group from 20-40 years old (from 10% in 2010 to 3% in 2017) and a slight increase in the number of patients with an age over 61 years old (from 22% in 2010 to 31% in 2017).

The main psychiatric comorbidity associated with the patients included in the study group was anxiety, measured through the Hamilton anxiety scale (tab. II).

TABLE II

Type of depression and the associated anxiety level

	2010	2017
Anxiety		
Mild Anxiety	16	20
Moderate anxiety	20	18
Severe anxiety	30	35
Depression		
Mild depression	0	0
Moderate depression	0	0
Severe depression	198	146

The Hamilton scale application for depression for the patients in the study group received a score of at least 27 points and the patients who did not get at least 27 points were not included in the present study. The average of the depression scores in 2017 for men was 32.25±2.19, and for anxiety of 23.62 ±5.83, and the average

value of VSH was 13.35±10.34. In regard to the women patients, in 2017 was registered a HAMD average of 32.04±2.23, and in the case of HAMA 26.3±1.33 with an average VSH value of 19.17±8.17. Following the same parameters, in 2010 the average of scores for depression calculated with the HAMD scale in the case of men was 32.41 ±2.52, with average anxiety of 25.6 ±4.36 and an average VSH of 21.11 ±7.27. In the women's case study, in 2010 the average HAMD value was 31.14 ±2.56, for HAMA 25.51 ±1.46 with an average value of VSH of 22.25 ±6.76.

Between the psychiatric comorbidities, the most frequently associated with depression for the patients included in the study, were the following: emotionally unstable personality disorder, addictive personality disorder, panic disorder, autolytic tendency, autolytic ideation, and dementia, according to the table below. In the following we will consider the autolytic ideation and autolytic tendencies, as a small sub-group with suicidal tendencies, to follow the associated particularities (tab. III).

TABLE III

Associated psychiatric comorbidities

Associated psychiatric comorbidities	2010	2017
TP emotional instability	7	12
TP addictive	15	18
Panic disorder	10	32
Autolytic tendencies	25	27
Autolytic ideation	12	18
Dementia	5	2

By analyzing the distribution between the age groups of the patients with suicidal risk, there noted significant differences between the young patients between 20-40 years, whereas a constant increase has been noted starting from only 4 patients in 2010 to 11 patients in 2017. The age group with the biggest number of patients with suicidal risk remains the over 60 years group for 2010, with 20 patients, as well as for 2017 with 22 patients, and for patients over 61 years old, a relatively constant number remained from 11 to 12.

We analyzed the women's age group with suicidal risk identified in the year 2017.

For the 14 patients, we identified with an average value for the HAMD score of 33 ± standard deviations 2.44, an average value of VSH of 24.9 ± standard deviations of 7.57, and a HAMA average value of 26.37 ± standard deviations of 1.3.

To identify and study the relationship between VSH and HAMD in the study group the coefficient *Pearson* was calculated at r=0.04, a value that suggests a moderate correlation between the 2 variables. The positive sign suggests that the low scored withing the first variable, correlates with the low scores in the second variable, average scores from the first variable associated with average scores in the second variable, and high scores in the first variable associated with high scores in the second variable. To establish the value of p the linear regression function from Excel was used, the significand threshold being of <0.05. It has been noted that the statistical analysis

ANOVA between the values of HAMD and VSH F(1.12)=0.5, at a p 0.1.

As the indicated value from the graphic above, in the case of women with suicidal risk selected in 2017, the higher the depression score HAMD the higher the value of VSH - that suggests that the inflammation status tends to go up.

Similarly, we analyzed the group of women with suicidal risk from 2010 and we identified an average value of HAMD of 32.181 ± 3.33 standard deviation, with an average value of VSH of 25.090 ± 6.33, standard deviation and a HAMA average value of 25.545 ± 1.47 standard deviation.

The Pearson coefficient was calculated, with an r=0.61, which suggests a powerful correlation between HAMD and the VSH value. The statistical analysis continues to evidentiate a p=0.05, statistically significant.

We concluded that in the cases of women with associated suicidal risk from 2010, the elevated values of HAMD are associated with the higher values of VSH, and we can conclude, at least for women, that depression is associated with a higher degree of inflammation.

In the men cases with associated suicidal risk from 2017, we identified an average HAMD score of 32.56 ± 2.15 standard deviation, with an average VSH of 16.75 ± 11.9 standard deviations and a HAMA value of 26.5 ± 1.54 standard deviation. We can observe an average value a lot lower than the VSH associated, compared with the women study group.

The calculation of the Pearson coefficient evidentiate a r=0.26, suggest a powerful correlation between HAMD and VSH. The linear regression function and statistical analysis ANOVA have identified a p=0.04 significantly statistic.

The graphic representation sustains the hypothesis according to which the highest HAMD values are associated with the over the average that tends to go towards the superior limit of VSH.

The men group from 2010 with a suicidal risk have the following particularities: average HAMD value of 32.41 ± 2.95, standard deviation, average VSH=20.67 ± 8.05 standard deviation and HAMA average =23.64 ± 4.22 standard deviation.

DISCUSSION

For women, the decreased state of anxiety in the last years is related to other factors. Therefore, we consider that the increased understanding of the factors that maintain the anxiety problems were acquired through efficient strategies of relaxation, with changes in the way of thinking that predisposes to anxiety and the correction of the behaviors that maintain anxiety.

Also, there have been acquired some strategies of developing positive emotions, and the positive side of life, strategies for prevention of the relapses with reduction of the symptoms of depression that come with anxiety.

Once the cytokines reach the cerebral level, they influence the ax involved in the psychopathology of depression by metabolically altering the neurotransmitter 5-HT, DA, and NA. Tryptophan is a component of serotonin and melatonin. Within the immune response of the T cells helper 1 (TH1) microglia and macrophages produce interleukin 1 (IL-1), interferon ɣ (IFN ɣ) and the necrosis tumor factor α that induce the production of indolamine 2,3-dyoxigenase (IDO) favoring the conversion of tryptophan in quinolinic acid, an agonist of the N-methyl-D-aspartic (NMDA) acid and kynurenic acid, the antagonist of NMDA (19).

One of the most debated associations in this field is the connection with the bilateral potential between depression and pain affecting the population at a global level. We are talking about the co-existence of almost 80% (20), contributing often to an increased mortality rate (21).

According to a report from the World Health Organisation, every year occur 800,000 deaths by suicide (22). The cultural taboos, as well as the fact that death by suicide is considered a criminal act in some countries can influence the statistics (23). In the present day, it is estimated that the suicide attempts are from 10 to 20 times more frequent than the actual number of deaths by suicide. The number of deaths by suicide as well as the attempted suicides is the result of a major severe psychiatric sufferance. The carried-out attempts of suicide carry with them an emotional burden that affects both the individual and the family for a long period (24).

Even though the pharmaceutical treatment and addressability for depressive patients with suicidal behavior are continuously rising, the frequency of suicides and suicide attempts does not register considerably lower rates. It is estimated that approximately 1.53 million deaths by suicide will be registered in 2020, an estimation that is at an alarming rate, and changes in the field are a must (25). Being able to assess suicidal behavior is a constant challenge for psychiatrists, consider the fact that most patients do not present the actual gravity of the symptoms, and diminish them. In some cases, the medical system cannot precisely detect the gravity of the phenomenon even though it is well known that 50% of these patients get in contact with the suppliers of medical services, several months before the first suicidal attempt (26).

In consequence, it is required an improvement within the methods of diagnosing the risk of suicide, access to more efficient options of treatment, and counseling towards suicidal patients (27, 28).

Here in our results, we showed that there is a cumulation of factors that can determine the bidirectional relationship between depression and inflammation. The mechanisms that are at the base of it are not fully known.

The inflammation hypothesis was under discussion more and more often lately, and the biological abnormalities in major depressive disorder were highlighted in numerous studies.

There is a cumulation of factors that can determine the bidirectional relationship between depression and inflammation, but the mechanisms that are at the base of it are not fully known.

CONCLUSIONS

The current data do not allow us to draw definitive and clear conclusions over the hypothesis about the inflammation in depression, but we can speculate a tendency and a repetitive pattern in this way.

From the statistical analysis of the groups studied, we understood that the average value of HAMD was relatively constant as well in men and women, without considerable variations over 7 years. The difference consists in a stronger association between the women with severe depression and a higher VSH, over men, whereas we can observe lower VSH values, but with tendencies towards the superior limit, a fact that supports the hypothesis of an association between depression with the inflammation status, especially in patients with suicidal risk.

NEWS

COMMON ALLERGY DRUG MAKES RESISTANT BACTERIA VULNERABLE TO ANTIBIOTICS

The common antihistamine loratadine-the active ingredient in over-the-counter medications such as Claritin, Alerclear, and Alavert-makes some species of antibiotic-resistant bacteria susceptible to antibiotics in lab experiments. To cope with the rise of these stubborn bacterial strains, clinicians often combine different antibiotics or prescribe them along with drugs that help prevent bacterial enzymes from degrading antibiotics. But for now, there are no drugs that increase bacterial susceptibility to existing antibiotics. “It’s totally unexpected to see an antihistamine compound have this effect” says chemist Steven D. Townsend of Vanderbilt University, who was not involved in the study. He adds that if the findings hold up in clinical studies, loratadine’s antibacterial activities “could be really powerful”. The researchers cultured varieties of *S. aureus* and *S. epidermidis*, including standard laboratory strains and ones isolated from hospital-acquired or community-acquired infections. They treated the bacteria with a common antibiotic, oxacillin, in the presence of loratadine and desloratadine, a bioactive metabolite of the drug. When treated with loratadine, *S. aureus* strains were 8 to 500 times as sensitive to the antibiotic. Desloratadine did not affect *S. aureus* susceptibility, and neither compound had any effect on *S. epidermidis*. Antibiotic resistance and biofilm formation are regulated by similar genetic mechanisms. Biofilms enhance drug resistance and are the main cause of catheter-associated infections. When the researchers tested the effects of applying the antihistamines to bacteria in culture, they found that loratadine blocked biofilm formation and broke up preformed biofilms of all *S. aureus* strains and of some *S. epidermidis* strains tested. The team then sought loratadine’s targets. Both microbes carry a gene named *stk* whose protein triggers the synthesis of antibiotic-blocking enzymes. Mutant *S. aureus* strains that lack *stk* were not made more sensitive to oxacillin by loratadine, suggesting the gene’s product could be loratadine’s target. Further studies in animal models will be needed to see if loratadine is effective against infections. Moreover, the authors add that loratadine—taken as a pill for allergies-is converted into desloratadine in the body, and the latter was ineffective in their experiments. “Loratadine could have applications as a topical ointment on burns or wounds” where it would not be metabolized, Blackledge says. (Jyoti Madhusoodanan, special to *C&EN , Chemical and Engineering News*, June 12, 2019,Volume 97, Issue 24 about the article *From Antihistamine to Anti-infective: Loratadine Inhibition of Regulatory PASTA Kinases in Staphylococci Reduces Biofilm Formation and Potentiates β-Lactam Antibiotics and Vancomycin in Resistant Strains of Staphylococcus aureus*. ANALYSIS OF THE NEWBORNS FROM HIV POSITIVE-MOTHERS IN A PERIOD OF THREE YEARS FROM THE REGIONAL HIV-AIDS CENTER IASI, ROMANIA (Abstract) **Aim:** With proper medication and regular monitoring, pregnant women with human immunodeficiency virus (HIV) can give birth to a healthy child. With the implementation of programs to prevent vertical transmission, the number of HIV-positive newborns has decreased significantly. The aim of this paper is to evaluate the HIV status of newborns perinatally exposed through the infection. **Material and methods:** We conduct a retrospective study on the HIV positive women registered at the "Sf. Parascheva" Infectious Disease Hospital from Iasi, which became mothers between 2017-2019. **Results**: During the three years mentioned period, 101 newborns from HIV positive mothers were included in the study, four being from untreated mothers. All the children received prophylactic antiretroviral compounds. At the end of the monitored period, two children had detectable viremia. **Conclusions**: Evaluation of HIV-positive mothers and prophylaxis of newborns during the evaluated period, which was conducted according to the protocol, lead to a low percentage of HIV-positive children. **Keywords:** MATERNAL-FETAL TRANSMISSION, ANTIRETROVIRAL THERAPY, PROFYLAXIS, HIV.

Human immunodeficiency virus (HIV) / acquired immune deficiency syndrome (AIDS) is more than a public health priority. It is a complex problem that affects all components of the society (1).

Although HIV infection is perceived as one of the most feared conditions, most infected couples (both partners being HIV positive) or serodiscordant couples want at least one child. From a medical point of view, due to the evolution of medicine, the risks of transmitting HIV infection from mother to fetus is much lower (2).

The detection of HIV-positive pregnant women is essential to prevent the transmission of the infection (3). The vertical transmission of the infection may occur during pregnancy, labor or birth delivery, or breastfeeding. Without treatment, about 15-30% of children born from HIV-positive mothers will become HIV infected during pregnancy or childbirth. Other 5-20% will

be infected by breastfeeding (4).

Maternal-fetal transmission in Romania has decreased dramatically since the beginning of the 1990s, from 45% to <3% at the beginning of 2018 (5). In the last years, two frequency peaks were registered, in 2010 (4.7%) and in 2013 (3%), so that in 2016, they registered the lowest value (0.7%). Among children (0-14 years), the vertical transmission path is on the 2nd place (6).

Epidemiological surveillance, antiretroviral treatment (ARV) and prevention of the maternal-fetal transmission of infection are performed according to national protocols, respecting the recommendations of the World Health Organization (WHO) (7). Programs to prevent vertical transmission started in the North-eastern part of Romania since 2004, due to the increasing number of cases of the virus transmission from mother to fetus (prenatal, perinatal, and postnatal). That is determined by the high incidence of HIV infection in young women with a low educational level, and also of the increasing number of injecting drug users (8).

A strategy consists in three components that are necessary to prevent the transmission of infection from mother to her child: preventing HIV infection among future parents, avoiding unwanted pregnancies among HIV-positive women, and preventing HIV transmission from HIV-positive mothers to their children during pregnancy, contractions, births, and breastfeeding (9).

MATERIAL AND METHODS

Studied patients

The monitoring sheets of HIV-infected pregnant women from the North-Eastern part of Romania were analyzed retrospectively, in order to highlight the status of the newborns, as well as to comply with the prophylaxis programs regarding the vertical transmission of the virus.

The study included females diagnosed with HIV who became pregnant and gave birth to live children during the study period. The exclusion criteria consisted of pregnancies that did not result in the birth of live children and the abortions.

Data analysis

The study summarized a period of three years, respectively from January 2017 to December 2019, and the data were obtained from the medical records of the patients from Iasi Regional HIV-AIDS Center.

Data were analyzed by descriptive statistics, where applicable. Statistical analysis was performed using *XLSTAT* version 2019 software.

RESULTS AND DISCUSSION

The Regional HIV-AIDS Center from Iasi, a center that is serving to the HIV-positive population from the North-Eastern region of Romania, is part of the St Parascheva Infectious Disease Hospital from Iasi.

Currently, in the records, there are more than 1440 patients, 46% of whom are female. Analyzing their monitoring sheets, we found that, during the aforementioned period, 101 patients became mothers. The largest group was represented by female between 26-35 years old (77.23%), and most of them were from urban areas (67.32%). If we look back, the average age of the mothers in the study group reminds us of the pediatric cohort from 1989-1992. Then over 13,000 children were infected with the HIV virus in Romanian hospitals. More than half of them still managed to survive, although no one gave them a chance (10). Today, they are between 28

and 31 years old and can live normally. Of the studied group, 52 (51.48%) females are part of that cohort.

Most women diagnosed with HIV are of childbearing age, which requires an increased need for choices about whether or not they want biological children. The opinions of the life partner, of the family members, the fear of stigmatization can significantly influence the decision. An additional factor is the fear of transmitting HIV to their child (11). The support of the attending physician associated with psychotherapy sessions can positively influence the decision of having a child (12).

The vulnerability of women living with HIV is higher than other population groups. This can be determined by the person's status, the social and economic context in which the person lives, and the stereotypes present in society (13). Also, the presence of comorbidities in people with HIV contributes to the increase of vulnerability and in the decisions about giving birth. For example, the association of infection with hepatitis B virus, an infection that can also be transmitted vertically from mother to fetus (14). The results of our study show that 6.93% (7 cases) associated HBV infection.

Once the decision to have a child has been made, careful monitoring is necessary to stop the transmission of the infection to the fetus. One of the components of the prophylaxis program concerns the administration of antiretroviral therapy to the mother (15). In our study, 97 (96.03%) of the pregnant women were monitored during pregnancy and received prophylactic treatment. Ninety of them throughout all pregnancy, 6 only in the last trimester of pregnancy, and in one case the monitoring began at birth, because the mother was tested for HIV at birth. The mother's ARV therapy is shown in first table.

TABLE I

Mother's ARV therapy

ARV therapy	No of patients (%)
KLT + CBV	58 (57,42%)
KLT + KIV	3 (2.97%)
KLT + RAL	2 (1.98%)
RAL + KIV	5 (4.95%)
RAL + CBV	2 (1.98%)
DRV/RTV + KIV	11 (10.89%)
DRV/RTV + ETV	2 (1.98%)
DRT/RTV + CBV	1 (0.99%)
DRV/RTV + 3TC	1 (0.99%)
FTC/TDF + RAL	3 (2.97%)
FTC/TDF + RIL	1 (0.99%)
CBV + KLT + RAL	1 (0.99%)
FTC/TDF + ATZ + RTV	1 (0.99%)
FTC/TNF + DRV/RTV	2 (1.98%)
DRV/RTV + 3TC + RAL	1 (0.99%)
DRV/RTV + ETV + RAL	1 (0.99%)
DRV/RTV + CBV + RAL	2 (1.98%)

KAL – Kaletra, CBV – Combivir, KIV – Kivexa, RAL – Raltegravir, DRV – Darunavir, RTV – Ritonavir, ETV – Etravirine, FTC – Emtricitabine,3TC – Lamivudine, RIL – Rilpirine, TDF – Tenofovir, AZT - Zidovudine

It consisted in a combination of Lopinavir – Ritonavir (Kaletra) with Zidovudine- Lamivudine (Combivir) throughout the pregnancy in 58 cases (57.42%), other antiretroviral regimens in 39 cases (38.61%) and in four cases (3.96%), no treatment regimen was administered, due to the mother's non-compliance or because the mother was tested for HIV at birth.

Thus, between 2017-2019, 101 children were born, 41 females (40.9%) and 60 males (59.40%). The distribution by years is shown in the second table.

TABLE II

Distribution of newborns from HIV-positive mothers by years

2017		2018		2019	
F (%)	M (%)	F (%)	M (%)	F (%)	M (%)
15(45.45%)	18(54.54%)	12(33.33%)	24(66.66%)	14(43.75%)	18(56.25%)

F – female, M – male

Another strategy to prevent maternal-fetal transmission is scheduled caesarean section (16). From the data obtained, we observed that the birth of the children in the study was by caesarean section in most cases, respectively 99 cases (98.01%), except for 2 children who were born through the natural way (1.98%), the mother was not previously diagnosed with HIV3.

In addition to maternal prophylaxis, child prophylaxis should be performed, with the risk of perinatal transmission being reduced to 0.4% in developed countries (17). Postexposure prophylaxis can offer protection against HIV infection even to babies of women who missed opportunities to be counselled and tested before or during pregnancy. The nevirapine and zidovudine regimen is safe and easy to implement (18). For all newborns from this study the prophylaxis was done with Zidovudine and Lamivudine in 98 cases, with Zidovudine only in 2 cases and in one case was associated Kaletra to Zidovudine and Lamivudine (tab. III). All babies received postexposure prophylaxis for a period of 6 weeks.

TABLE III

Distribution of newborns from HIV-mother by ARV prophylaxis

ARV prophylaxis	2017	2018	2019
AZT + 3TC	31	36	31
AZT	1	0	0
AZT + 3TC + KLT	1	0	1

ARV – antiretroviral therapy, AZT – Zidovudine, 3TC – Lamivudine, KLT – Kaletra

As soon as the fetus is born, they are under regular monitoring to evaluate the viral load and the number of CD4 lymphocytes, as well as serological testing. Monitoring takes place at birth, at one month, at 3, 6, 9, 12 and 18 months, respectively. The HIV status of a child is finally declared at 18 months, after a PCR- HIV test. A patient of 18 months who comes from an infected mother and who has positive serological tests is considered HIV infected (19,20).

By the time this article was written, the surveillance period for 78 children had ended, with 76 having undetectable viremia at the age of 1 and a half. Two children had

detectable viremia at birth, respectively they remained positive at 18 months. Two children remained positive at 18 months and the further therapy for them consisted of Zidovudine + Lamivudine + Nevirapine. For some newborns in 2019, the surveillance period is not over. Twenty-three children continue to be under clinical and para-clinical supervision. However, the data obtained so far show that none show detectable viremia, which indicates the good evolution of the cases and the non-transmission of the infection from mother to fetus.

CONCLUSIONS

The evaluation of HIV-positive mothers and prophylaxis of newborns during the evaluated period was conducted according to the protocol, which resulted in a low percentage of HIV-positive children (1.9%).

All pregnant women in vulnerable populations should have the same access to services during pregnancy to prevent the transmission of HIV from mother to fetus. Preventing the vertical transmission of HIV aimed to reduce the incidence of this pathology.

In this epidemiological context, the issue of transmitting the infection from mother to fetus remains current, which is why the monitoring of this phenomenon should be continued in the coming years.

With proper medication and regular monitoring, pregnant women infected with the human immunodeficiency virus (HIV) can give birth to a healthy child. With the implementation of programs to prevent vertical transmission, the number of HIV-positive newborns has significantly decreased.

CONFLICT OF INTERESTS AND FUNDING

The authors declare that there is no conflict of interest and they received no specific funding regarding this scientific research.

NEWS

HEARING LOSS IN RHEUMATOID ARTHRITIS

Although hearing loss is not officially recognized as an extra-articular manifestation of rheumatoid arthritis, it is the subject of many studies that investigate its association with this disease. A recent systematic review and meta-analysis explored 12 such observational studies which included a total number of 20,022 patients and 79,244 controls. The authors concluded that rheumatoid arthritis is significantly associated with increased odds (OR 3.42, 95% CI 2.50-4.69) compared to controls and with increased risk of sensorineural hearing loss (RR 2.28, 95% CI 1.88-2.76), while there is no association with conductive hearing loss or mixed hearing loss. This can be due to direct damage to the cochlea by autoantibodies, vasculitis affecting the cochlea or the cochlear nerve blood supply, or an iatrogenic mechanism. Therefore, an early screening of rheumatoid arthritis patients with pure tone audiometry could be of value. (Chaitidis N, Theocharis P, Festas C, Aritzi I. Association of rheumatoid arthritis with hearing loss: a systematic review and meta-analysis. *Rheumatol Int* 2020; 40: 1771-1779).

THE ROLE OF COMPREHENSIVE GERIATRIC ASSESSMENT IN THE COMPLEX MANAGEMENT OF SENIOR PATIENTS WITH HIP FRACTURE

THE ROLE OF COMPREHENSIVE GERIATRIC ASSESSMENT IN THE COMPLEX MANAGEMENT OF SENIOR PATIENTS WITH HIP FRACTURE. (Abstract): The increased incidence of hip fracture in the frail elderly patients requires the development of differentiated care, adapted to their physical, psychological and emotional profile. Pre- and postoperative comprehensive geriatric assessment (CGA) is the most accurate tool for developing a personalized therapeutic and care plan. **Aim:** To investigate the consequences of the surgical treatment of hip fractures on senior patients using CGA preoperatively and in the immediate postoperative period. **Material and methods:** The prospective study, from which we present the preliminary data, was conducted on a group of 95 patients admitted in the Trauma Clinic with hip fracture. Of these, only 59 underwent CGA preoperatively and 48 hours postoperatively. Particular attention was given to frailty - evaluated with Groningen Frailty Index (GFI), neurocognitive status - evaluated with Mini-Mental State Examination (MMSE), and psycho-emotional status - evaluated with Geriatric Depression Scale (GDS). **Results:** Analyzing the GFI scores ($p = 0.014$) it was found that of the preoperatively robust patients 71.4% became frail postoperatively. No statistically significant differences in cognitive and psycho-emotional status were found in the immediate postoperative compared to the initial preoperative assessment, probably due to the small sample size. **Conclusions:** The results of this study confirm the importance of evaluating the degree of frailty for the prediction of the postoperative evolution of hip fractures in senior patients. **Keywords:** COMPREHENSIVE GERIATRIC EVALUATION, HIP FRACTURE, SENIOR PATIENTS, SURGERY.

Falls represent a frequent cause of morbidity, mortality and decreased QoL in senior population, as they are associated with severe physical and psychological trauma. Statistics report that 30% of the elderly fall annually, and more than half of this group fall several times a year (1-4). Hip fractures are among the most frequent types of traumas in aged people, fractures caused by backward falls being increasingly common (5, 6).

In this vulnerable population, a traumat-

ic event is associated with the aggravation of functional decline (frailty, sarcopenia), social withdraw, anxiety, depression, prolonged bed immobilization, fear of future recurrent falls, and increased use of medical services (7). These are the main reasons why these patients should be hospitalized immediately in a Trauma Department - preferably an integrated orthogeriatric clinic - in order to identify the best therapeutic approach. The surgical treatment is always preferred over immobilization in a cast (8-11). The decision of whether or not to perform surgery in these patients should be made according to the results of the geriatric assessment, preferably the CGA (12-14). The postoperative recovery of these patients relies on their degree of frailty, resilience, and family support, important factors that will help them to fulfill the physical and psychological program designed by the geriatric team. The prognosis of recovery in these patients is strongly related to the geriatric evaluation (15-17).

MATERIAL AND METHODS

We present a prospective study carried out between June 2019 and March 2020 on a group of senior patients admitted with hip fracture in the Orthopedics-Traumatology Clinic of the Iasi County "St. Spiridon" Emergency Hospital. The CGA was performed by a geriatric team in the preoperative period and 48 hours postoperatively. Special attention was paid to assessing the degree of frailty using GFI, neurocognitive status using MMSE, and psycho-affective status using GDS. Of the 95 patients, only 59 (62.1%) patients were assessed postoperatively, due to the epidemiological context that restricted multidisciplinary access and the inability of patients to collaborate postoperatively (mainly due to significant pain).

The informed consent was obtained from all patients prior to the completion of the questionnaires by the same trained medical team (18).

Data were analyzed using *SPSS 18.0* software. ANOVA test, F test (ANOVA), multivariate analysis, ROC curve, χ^2 and *t-Student's* test, Kruskall-Wallis and Pearson correlation were used for the quantitative interpretation of the data. Statistical significance was set at $p < 0.05$, (95% confidence interval).

RESULTS

The analyze of the demographic data showed that the age of the study patients ranged from 61 to 96 years, with a mean of 77.58 (± 9.02) years, close to the median (78 years), suggesting that age-range was homogeneous, so tests of statistical significance could be run.

Of all study patients, 50.8% were older than the median, 64.4% were male, and 61% were not married (tab. I).

TABLE I

Descriptive demographic data

Demographic characteristics	n = 59
Mean age ± SD, years (median/min-max)	77.58 ± 9.02 (78/61-96)
≥ 78 years, n (%)	30 (50.8%)
Male, n(%)	38 (64.4%)
Unmarried / divorced / widowed, no (%)	36 (61.0%)

Preoperative assessment – statistical indicators

Preoperatively, the GFI score ranged from 0 to 12; the mean 5.20 ± 3.11 was close to the median value (score = 4), and a value < 2 for skewness suggested that the

range of GFI scores was homogeneous (tab. II).

The score for cognitive assessment (MMSE) ranged from 5 to 30; the mean 22.20 ± 5.73 was close to the median value (score = 23), and a value of >-2 for skewness suggested that the preoperatively recorded range of MMSE scores was homogeneous (tab. II).

The score for emotional assessment (GDS) was in the range 0-14; the mean 6.34 ± 3.58 was close to the median value (score = 6), and the value of >-2 for skewness suggested that the preoperatively recorded range of GDS scores were homogeneous (tab. II).

TABLE II

Statistical indicators of preoperatively monitored scores

Score		MMSE	GDS	GFI
Evaluations		59	95	59
Mean		22.20	6.34	5.20
Median		23	6	4
Standard Deviation		5.73	3.58	3.11
Variance		25.81	12.85	9.68
Skewness Test		-0.609	-0.047	0.376
Std. Error of Skewness		0.311	0.311	0.311
Minimum		5	0	0
Maximum		30	14	12
Percentile	**25**	17	4	3
	50	23	6	4
	75	27	9	8

Postoperative assessment – statistical indicators

Postoperatively, the GFI score ranged from 1-13; the mean 7.39 ± 3.20 was close to the median value (score = 7), and the value of > -2 for skewness suggested that the range of GFI scores was homogeneous (tab. III).

The postoperative MMSE score ranged from 8 to 30; the mean 21.58 ± 5.71 was close to the median value (score = 22), and the value of > -2 for skewness suggested that the range of MMSE scores was homogeneous (tab. III).

The postoperative GDS score ranged from 1 to 14; the mean 6.76 ± 3.32 was close to the median (score = 7), and the value of >-2 for skewness suggested that the range of GDS scores was homogeneous (tab. III).

The homogeneity of preoperative and postoperative MMSE, GDS and GFI scores allowed us to use significance tests for continuous variables.

The percentage distribution of cases with cognitive (p = 0.052) or emotional (p = 0.157) impairment had slightly increased postoperatively (tab. IV).

The percentage of cases with frailty increased significantly postoperatively, from 64.4% preoperatively to 86.4% postoperatively (p = 0.002) (tab. IV).

TABLE III

Statistical indicators of postoperatively monitored scores

Score		MMSE	GDS	GFI
Evaluation		59	95	59
Mean		21.58	6.76	7.39
Median		22	7	7
Standard Deviation		5.71	3.32	3.20
Variance		32.59	11.01	10.21
Skewness Test		-0.499	-0.022	-0.010
Std. Error of Skewness		0.311	0.311	0.311
Minimum		8	1	1

severe moderate mild normal	1 (1.7%) 17 (28.8%) 20 (33.9%) 21 (35.6%)	3 (5.1%) 16 (27.1%) 23 (39.0%) 17 (28.8%)	Wilcoxon Signed Ranks Test	0.052
GDS Emotional impairment	6.34±3.58	6.76±3.32	Paired Samples T test	0.123
very depressed mildly depressed normal	7 (11.9%) 31 (52.5%) 21 (35.6%)	8 (13.6%) 66 (55.9%) 18 (30.5%)	Wilcoxon Signed Ranks Test	0.157
GFI	5.20±3.11	7.39±3.20	Paired Samples T test	0.001
frail robust	38 (64.4%) 21 (35.6%)	51 (86.4%) 8 (13.6%)	Wilcoxon Signed Ranks Test	0.002

Analyzing the postoperative GFI scores, the following was found (p = 0.014) (fig.1): 71.4% of the preoperatively robust patients became frail postoperatively.

After plotting the ROC curve, it was found that the marital status (AUC = 0.632; 95% CI: 0.442-0.823; p = 0.232); emotional score (AUC = 0.735; 0.579-0.891; p = 0.034) and preoperative frailty (AUC = 0.767; 0.635-0.900; p = 0.016) are good predictors of postoperative frailty (fig. 2, tab. V).

DISCUSSION

In the context of demographic aging, the incidence of hip fractures will increase directly proportional to life expectancy, risk of falling, and tendency to osteoporosis. On average, one in three patients dies within the first year after suffering this type of fracture, and in over half of these patients mobility is still limited one year after trauma. Age-related issues, such as psycho-emotional status, frailty, sarcopenia, and others, indicate that the appropriate treatment is a complex one, and patient assessment in the pre- and postoperative period must be a holistic one. The risks for patients to develop severe complications and loss of functionality are considerable and often associated with high treatment costs (19-22).

The assessment of the personal status of the injured patient pre and postoperatively using a most reliable geriatric tool (CGA) is an important predictor of the physical and psychological resilience of the patient, an essential component of the recovery period (23, 24). Of the many aspects of the CGA our study focused on frailty, cognition impairment and depression as predictors of postoperatively evolution.

Most studies report frailty as a major component in the occurrence of postoperative adverse outcomes in senior patients (25-28). Our results confirm these data, alarming increase of frailty being recorded postoperatively in the preoperatively robust patients. Thus, the need for complex and sustained treatment of frailty through early rehabilitation: physical therapy, prevention of protein-calorie malnutrition and sarcopenia, and psychological support.

Congruent results suggest that cognitive impairment, was found to be correlated with limited functional gains and poor postoperative rehabilitation outcomes. Therefore, cognitive impairment has traditionally been regarded as an obstacle in geriatric rehabilitation. Specific studies in senior patients with hip fractures have led to the assumption that they should not be considered suitable candidates for active rehabilitation programs. It seems obvious that cognitive status plays a major role in the success of rehabilitation. A significant number of elderly patients undergoing rehabilitation programs associate cognitive deficits, therefore it is important to measure the success of rehabilitation in the senior patients with cognitive impairments who have suffered a hip fracture (29-32).

Our results do not confirm these data, the cognitive function of our patients being preserved independently of the impact of the fracture and/or surgical treatment. We consider that our data are influenced by the small sample size, and we intend to continue the study as soon as the epidemiological situation allows it.

Regarding the psycho-emotional status, some data suggest that in the senior patients who underwent hip fracture surgery, depression symptoms were associated with the underlying Alzheimer's disease and postoperative delirium. According to these results, the initially mild depression symptoms were the strongest predictor of postoperative delirium, representing a prodrome of dementia (33). Our results are not statistically significant for the psycho-emotional component. Thus, emotional status does not undergo the deconditioning inherent in trauma or surgery. In this respect, the literature indicates that fracture type or the degree of post-traumatic disability are not as important predictors of

psycho-emotional impairment in the post-operative period as the state of apathy. The only direct relationship is between depression and fall risk. The same studies highlighted a correlation between hip fracture, depression and 5-HTTLPR genotype, indicating a genetic predisposition for the development of an emotional impairment (34, 35).

CONCLUSIONS

Integrated orthogeriatric treatment should be the standard approach to the multidimensional needs of senior patients with hip fracture. Patient characteristics play a decisive role in recovery outcomes. For clinicians, it is critical to gain a clear perspective of the underlying factors influencing the poor outcome after a hip fracture, such as the degree of frailty and psycho-emotional impairment.

Preoperative assessment should accurately estimate the degree of frailty, cognitive and psycho-emotional status, as any degree of recorded dysfunction is a negative predictor for all components of post-operative recovery. Frailty assessed as GFI score > 4 is decisively correlated with the traumatic and surgical impact, independent of patient preoperative status. In this respect, cultivating the resilience-enhancement interventions is the primary goal of orthogeriatric treatment. The holistic, multidisciplinary, and at the same time individualized approach of the senior patients who suffered a hip fracture prevents the negative prognostic value of any cognitive-emotional prototype, but also of any frailty phenotype.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest, and they received no specific funding regarding this scientific research.

NEWS

REGIONAL DIFFERENCES IN THE IMPACT OF DIABETES ON POPULATION HEALTH

The study carried out in the USA evaluated regional disparities in the influence of diabetes on population health and examined life expectancies at age 50 between population with diabetes and healthy population and life quality among the population with diabetes among native-born Americans by birth region and current residence. Using data on a cohort of 17,686 native-born individuals from the Health and Retirement Survey (1998-2014), the authors applied a Bayesian multistate life table method to estimate life expectancies at age 50 between population with diabetes and healthy population by each birth/current region combination. They estimated the proportion of life remaining without either chronic conditions or disabilities as a quality-of-life measure and the probabilities that one region is worse than the other in terms of different health outcomes. As results, the authors showed that, at age 50, persons with diabetes were expected to live on average 5.8-10.8 years less than their healthy equivalents across regions. Diabetes had the greatest influence on life expectancy for older adults who lived in the South at the time of interviews. Persons with diabetes born in the South were more likely to have developed chronic conditions or disabilities and spent greater proportions of life with these two issues compared to other regions. ACCURACY OF AST TO PLATELET RATIO FOR PREDICTING LIVER FIBROSIS IN PATIENTS WITH CHRONIC HCV INFECTION AFTER VIRAL ERADICATION (Abstract): Determining the stage of fibrosis is an essential element of chronic hepatitis C (HCV) management. This study aims to evaluate aminotransferase to platelet ratio (APRI) score in comparison with Vibration-Controlled Transient Elastography (VCTE) for assessing the severity of liver disease in HCV-infected patients. **Material and methods:** We retrospectively enrolled 293 HCV-infected patients with different stages of fibrosis who achieved sustained virological response (SVR) after direct-acting antivirals (DAAs) therapy, which have been evaluated by VCTE from 1st September 2020 to 30th July 2021. **Results:** Two hundred and ninety-three patients (72.7% females, mean age of 61.75 ± 10.87 years, and mean BMI of 27.85 ± 4.63 kg/m^2) were evaluated. As estimated by VCTE, 44 (15%) of patients were without liver fibrosis (F0), 80 (27.3%) with F1 (mild), 39 (13.3%) with F2 (significant), 43 (14.7%) with F3 (advanced) liver fibrosis, and 87 (29.7%) with F4 (cirrhosis), with a mean value of liver stiffness measurements (LSM) of 10.17 ± 7.42 kPa. The APRI score has a positive correlation with the LSM score (p=0.047), predicting severe liver disease adequately. The optimal receiver operator curve (ROC) for predicting advanced fibrosis was > 1.15 (area under the curve [AUC] 0.79, 95% CI 0.71-0.83; p < 0.001) with a sensitivity (Ss) of 82.5%, specificity (Sp) 28%, a positive predictive value (PPV) of 72%, and negative predictive value (NPV) of 81%. **Conclusions:** APRI score can predict well the advanced liver fibrosis and cirrhosis and can be a useful non-invasive biochemical marker for resource-limited management of HCV-infected patients.
Keywords: CHRONIC HEPATITIS C, VIBRATION-CONTROLLED TRANSIENT ELASTOGRAPHY, AMINO-TRANSFERASE TO PLATELET RATIO.

Chronic hepatitis C (HCV) is one of the most common causes of liver cirrhosis and hepatocellular carcinoma and a growing global public health problem, affecting approximately 71.1 million of people worldwide (1). The new therapy with direct-acting antivirals (DAAs) had revolutionized the treatment of HCV, with more

than 95% of the patients achieving sustained virological response and a very good safety profile (2).

According to current guidelines, an evaluation of liver fibrosis with non-invasive methods in HCV-infected patients is required prior to therapy (3). This recommendation is based on the residual risk of hepatocellular carcinoma and further decompensation of liver cirrhosis in those with advanced/severe fibrosis, even after viral clearance (4).

Up to this point, liver biopsy (LB) has been considered traditionally the "imperfect" gold standard method for the staging of liver fibrosis. However, LB is an invasive procedure, with several limitations (high cost, sampling errors, intra-, and inter-observer variability, variable accessibility, and a low but real risk of morbidity and mortality), which led to the development of non-invasive methods such as Vibration-Controlled Transient Elastography (VCTE) with a high accuracy, currently being the most frequent imaging method for the evaluation of liver fibrosis in United States of America (5, 6). However, due to its high cost and limited availability in low- and middle-income countries, the use of VCTE could be replaced with surrogate markers such as the APRI or FIB-4 score (7, 8). The main advantages of these biochemical markers are the low costs and wide availability (9). In a recent study, Wong *et al.* found that the cut off value of 0.5 for APRI score predicted the existence of advanced fibrosis in 100% of the cases, thus highlighting the efficacy of this score (10). Moreover, APRI score is recommended by World Health Organization (WHO) for the evaluation of liver fibrosis in limited resources-areas (7-Sripongpun). However, data regarding the correlation of APRI score and VCTE are scarce and the need for the validation of APRI score in different patient populations is still required (11).

Hence, the aim of this study was to evaluate the diagnostic accuracy of APRI score compared with VCTE in staging the liver fibrosis in Romanian HCV-infected patients. As a secondary outcome, we aimed to determine the best cut-off values for APRI score to predict advanced fibrosis or cirrhosis.

MATERIAL AND METHODS

This is a retrospective study from a tertiary referral hospital in North-East of Romania that included 293 consecutive patients with chronic HCV infection and different stages of fibrosis who achieved SVR after DAA therapy, between 1st September 2020 and 30th July 2021. DAA regimens were either Paritaprevir/Ritonavir, Ombitasvir and Dasabuvir (PrOD), Ledipasvir/Sofosbuvir (LED/SOF) or Elbasvir/Grazoprevir (ELB/GRZ).

Demographic data, anthropometric measurements, blood tests and FibroScan evaluations were recorded for all patients. Reliable VCTE data was defined by following criteria: at least 10 valid measurements, and an interquartile range $\leq$ 30%. LSM results were expressed in kilopascals (kPa) ranging from 1.5 to 75 kPa, with cut-off values for fibrosis as follows: F0 (without), F1 (mild), F2 (significant), F3 (advanced) fibrosis, and F4 (cirrhosis); $\leq$ 5.5, 5.6-7.1, 7.2-9.4, 9.5-12.4, $\geq$ 12.5 kPa, respectively. APRI score was calculated using the proposed formula: APRI = [(AST level/ULN)/platelet count (109 /L)] × 100.

Patients with non-HCV related liver disease, coinfection with hepatitis B virus (HBV) or human immunodeficiency virus (HIV), HCC or other malignant pathologies, decompensated liver cirrhosis, acute

hepatitis, pregnancy, women in nursing period, incomplete or invalid FibroScan assessments, were excluded.

All patients signed the informed consent. Our study was conducted according to the criteria established by the Declaration of Helsinki.

Statistical analysis

All data were analyzed using *SPSS software version 22.0* (IBM SPSS Inc, Chicago, IL, USA). Continuous variables are expressed as median and interquartile/median range (IQR) or as mean ± standard deviation (SD). For comparing group's variables were used Student t-test for continuous variables, or *Chi-squared test* for comparing qualitative data as appropriate. One-way *ANOVA* was considered appropriate to assess the difference in APRI score values according to the fibrosis stages, while for checking the association between two variables *Pearson* (r) coefficient of correlation was used. Diagnostic performance of APRI score compared to TE was analyzed by constructing the receiver operator characteristic (ROC) curve, obtaining sensitivity (Ss), specificity (Sp), positive predicting value (PPV), and negative predicting value (NPV). A p value < 0.005 (two-tailed) was considered to be significant.

RESULTS

This study included 293 consecutive patients with chronic HCV infection and different stages of fibrosis, mostly females (72.7%), mean age 61.75 ± 10.87 years with mean BMI 27.85 ± 4.63 kg/m2. All patients were treated with DAAs and obtained SVR. One hundred thirty (44.3%) patients received PrOD, 120 (40.9%) LED/SOF and 43 (14.8%) ELB/GRZ. The mean LSM value was 10.17 ± 7.42 kPa, and the mean APRI score was 1.14 ± 3.91 (tab. I).

TABLE I

Baseline characteristics of the study population

Characteristics	Value
Gender (female), n (%)	213 (72.7)
Age, years	61.75 ± 10.87
BMI (kg/m^2)	27.85 ± 4.63
Platelet count (x10^3/cm^3)	177 ± 103
Fasting plasma glucose (mg/dL)	107.8 ± 35
ALT (U/L)	27.94 ± 23.89
AST (U/L)	28.34 ± 18.93
GGT (U/L)	37.29 ± 31.73
ALP (U/L)	95 ± 53.74
Total bilirubin (mg/dL)	1.14 ± 0.83
Total cholesterol (mg/dL)	186.62 ± 44.37
Triglycerides (mg/dL)	119 ± 57.91
Albumin (g/dL)	4.24 ± 0.51
LSM (kPa), median (IQR)	10.17 ± 7.42
APRI score	1.14 ± 3.91

BMI, body mass index; INR, international normalized ratio; ALT, alanine aminotransferase; AST, aspartate aminotransferase; GGT, gamma-glutamyl transferase; ALP, alkaline phosphatase; LSM, liver stiffness measurement; APRI, aspartate aminotransferase to platelet ratio

According to LSM, 44 (15%) patients had no liver fibrosis (F0), 80 (27.3%) patients had F1 (mild), 39 (13.3%) had F2 (significant), 43 (14.7%) patients had F3 (advanced), and 87 (29.7%) patients had F4 (cirrhosis).

TABLE II
APRI score in different stages of liver fibrosis

Liver fibrosis stages based on LSM		APRI	
Stage	**n (%)**	**Mean ± SD**	**p-value**
F0	44 (15)	0.34 ± 0.29	0.002
F1	80 (27.3)	0.41 ± 0.42	
F2	39 (13.3)	0.35 ± 0.16	
F3	43 (14.7)	1.32 ± 3.47	
F4	87 (29.7)	2.48 ± 6.55	

TABLE III
Comparison between APRI score and different stages of liver fibrosis

Liver fibrosis stages	p-value
F0 *vs.* F1	0.348
F0 *vs.* F2	0.801
F0 *vs.* F3	0.066
F0 *vs.* F4	**0.003**
F1 *vs.* F2	0.444
F1 *vs.* F3	**0.022**
F1 *vs.* F4	**0.004**
F2 *vs.* F3	0.087
F2 *vs.* F4	**0.045**
F3 *vs.* F4	0.190

We found significant statistical differences of APRI score between different fibrosis stages based on LSM (p<0.001) (tab. II). The differences remained highly significant when the mean APRI score value was compared between F0 *vs.* F4 (p=0.003), F1. *vs.* F3 (p=0.022), F1 *vs.* F4 (p=0.004), and F2 *vs.* F4 (p=0.045) (tab. III). Moreover, the APRI score had a positive correlation with AST (p = <0.001), ALT (p = 0.001), and LSM score (p=0.047), and a negative significant correlation with total cholesterol (p = <0.001) and albumin (p=0.022).

The optimal receiver operator curve (ROC) of the APRI score for diagnosing advanced fibrosis was calculated as > 1.15 (area under the curve [AUC]=0.79, 95% CI 0.71-0.83; p < 0.001) with a sensitivity (Ss) of 82.5%, specificity (Sp) 28%, a predictive positive value (PPV) 72%, and negative predicting value (NPV) of 81% (fig. 1).

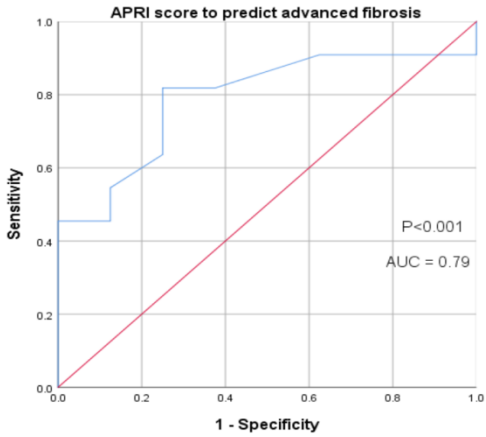

Fig. 1. Performance of APRI score in the prediction of advanced liver fibrosis (F3/F4) according to LSM

DISSCUSION

The outcome of chronic HCV infection varies significantly from patient to patient, depending on the level of fibrosis and viral status at the time of diagnosis. Recent years brought an extraordinary progress in the management of HCV infection, by introducing the new DAAs in the eradication strategies (12). Still, even after viral clearance, the severity of liver fibrosis needs to be acknowledged in order to evaluate the prognosis of the liver disease. There are several non-invasive methods to determine the severity of fibrosis which allow bypassing LB, previously known as the gold standard, nowadays leaving behind due to numerous shortcomings. In this regard, we chose to analyze the APRI score based on

consistent data showing its usefulness in predicting liver fibrosis. According to recent data, the APRI score has the best accuracy of all serum markers for the identification of advanced fibrosis and cirrhosis in patients with chronic hepatitis, demonstrating an excellent ability to discriminate between F3 and F4 (13). Moreover, a recent meta-analysis showed a significant association between increased APRI and the occurrence of HCC in patients with chronic hepatitis of various etiologies, demonstrating the usefulness of the APRI score in risk stratification in patients with chronic HCV infection (14).

In a large cohort study consisting of 3619 patients with HCV or HBV chronic infection, Wong et al demonstrated that APRI score has similar predictive value as LSM for advanced fibrosis (7). In line with these results, our study showed that APRI and LSM strongly correlated especially when comparing F0 *vs.* F4 and F1 *vs.* F4. Despite the similar findings between our study and the aforementioned, the fact that there are different cut-offs of TE in HBV *vs.* HCV, must be kept in mind (15). A more recent German study which analyzed a similar group as ours, consisting of 260 patients with HCV infection treated with DAAs, concluded that liver fibrosis regresses significantly after SVR (16). Although this was not initially an objective of the study, the authors found that APRI strongly correlated with TE, highlighting the efficacy

We found a good performance of APRI score in the prediction of advanced liver fibrosis (F3/F4) according to LSM. Considering a cut-off value of > 1.15, the PPV and NPV for APRI were 72% and 82%, respectively. In a prospective cross-sectional study, Mendes *et al.* showed that for advanced fibrosis, an APRI score less than 1 had a NPV of 81% (AUROC 0.80) whilst for a cut off above 2, the specificity for F ≥3 was 93% (17). Furthermore, the authors compared the performance of APRI *vs.* LB for predicting significant fibrosis and cirrhosis and found a slightly decreased accuracy of APRI (AUROC 0.78 and 0.82, respectively).

The main strength of our study is represented by the comparative analysis between LSM and APRI, which underlines the possibility of replacing the TE evaluation with this simple and widely available serum score. The limitations are represented by the lack of data regarding fibrosis stages assessed by both methods before the start of DAAs and also, we did not calculate the FIB-4 index, which could've been useful to compare with predictive power of APRI.

CONCLUSIONS

Considering the decreased availability of TE in some areas, APRI score is a good surrogate marker for liver fibrosis, with several advantages as low cost and simple to use in clinical practice. As the number of HCV-cured patients will dramatically increase and will require simpler ways to assess liver fibrosis.

IMPLICATIONS OF LIPID AND CARBOHYDRATE METABOLISM IN PERIODONTAL DISEASE ASSOCIATED WITH DIABETES, CARDIOVASCULAR AND NONALCOHOLIC FATTY LIVER DISEASE (Abstract): The systemic inflammatory response in periodontal disease is characterized by the presence of inflammatory mediators. The systemic inflammatory response positively influences the risk of developing diabetes and its complications, atherosclerotic diseases and other chronic conditions. Metabolic syndrome is a consequence of the modern lifestyle, an accumulation of metabolic abnormalities that increase the cardiovascular risk. Abnormal distribution of adipose tissue with obesity, insulin resistance, and dyslipidemia are some of these abnormalities but also increased blood pressure, atherogenic dyslipidemia, hypertension, and pro-thrombotic and pro-inflammatory status are other conditions. The study's main **objective** was to evaluate the hypothesis that inflammatory changes in gingival tissue are correlated to lipid and carbohydrate metabolism abnormalities in patients with diabetes mellitus (DM), cardiovascular disease (CVD), and nonalcoholic fatty liver disease (NAFLD). The medical records of 181 subjects were used in this retrospective study. The **results** suggested that periodontal disease can influence the systemic level of inflammatory mediators in patients with systemic diseases (DM, CVD, and NAFLD) by mechanisms that rely on oral microbial flora exposure and control. **Conclusions**: by influencing lipid and carbohydrate metabolism, NAFLD is closely correlated to cardiovascular disease or diabetes, and study into these factors in patients with periodontal disease helps to highlight the association between these diseases. **Keywords**: SYSTEMIC CONDITION, PERIODONTAL DISEASE, METABOLIC SYNDROME, DIABETES MELLITUS, CARDIOVASCULAR DISEASE, LIVER DISEASE.

The two-way relationship between periodontal tissue inflammation and a number of systemic conditions as risk factors, such as diabetes, cardiovascular disease, obesity, and liver disease, can be supported by studies that have evaluated metabolic disorders

in these patients (1).

Liver disease such as viral hepatitis or nonalcoholic fatty liver disease are often diagnosed in patients who have other comorbidities, such as cardiovascular disease. This association of these systemic diseases is frequently involved in the death of people who have been diagnosed with these conditions (2).

The endocrine system in the body achieves control in organs and tissues and thus establishes metabolism and weight (3, 4), Frequently associated dyslipidemia and obesity are risk factors for abdominal surgery due to the association with ischemic heart disease, hypertension, diabetes and respiratory failure (5).

Studies have shown that about 40-80% of variations in blood lipids are related to genetic factors (6, 7, 8). The increased incidence of type 2 diabetes is closely related to the presence of obesity but can also occur independently of this (9, 10).

There are many complications caused by diabetes with oral manifestations that require treatment appropriate to the patient's needs: oral infections, periodontitis or gingivitis. (11)

Glycosylated hemoglobin is a test that indicates a patient's glycemic control. Maintaining glycosylated hemoglobin < 7% can prevent cardiovascular complications, with a high risk of death for diagnosed patients (12, 13, 14).

Bleeding on probing is strongly associated with some systemic inflammatory mediators, in patients with coronary heart disease, liver diseases and periodontitis. This association reflects the potential of local periodontal inflammation for the development of systemic inflammation (15, 16, 17).

Liver disease such nonalcoholic fatty liver disease is associated with components of the metabolic syndrome: obesity, diabetes and insulin resistance, high blood pressure and dyslipidemia (18, 19).

As a major objective of the study, we will verify the study hypothesis inflammatory changes occurs within gingival tissue in correlation with disturbances related to lipid and carbohydrate metabolism in patients with diabetes (DM), cardiovascular diseases (CVD), nonalcoholic fatty liver disease (NAFLD).

The specific objectives are related to: analysis of demographic data of the group of patients, to highlight the role of sociodemographic factors related to gender, age, environment of origin in the evolution of periodontal disease and diabetes, cardiovascular disease, nonalcoholic fatty liver disease; evaluation of the clinical parameters of the periodontal status, in order to highlight the modification of the preexisting clinical picture of the periodontal diseases under the influence of the systemic pathology due to diabetes, cardiovascular diseases, nonalcoholic fatty liver disease.

MATERIAL AND METHODS

This retrospective study was conducted on a medical record of 181 subjects, selected from subjects who addressed the Periodontology Departments of the University of Medicine and Pharmacy of Craiova, Romania, between 2018 and 2020. The inclusion criteria for groups: the history of treatment for periodontitis, minimum age 25 years. Patients declared medically diagnosed by a specialist to have DM, CVD or NAFLD were included in the test groups. The age of the patients ranged from 28 to 68 years, the mean age being 47.33 years. The gender distribution of the patients consisted of 80 females (44.2%) and 101 males (55.8%), divided into four groups, for data analysis

and comparison, depending on systemic pathology (DM, CVD or NAFLD) in association with periodontal disease and another group of systemically healthy patients with periodontal disease. We will consider P group - patients with periodontal disease (35 patients), P+DM group - patients with diabetes and periodontal disease (64 patients), P+CVD group - patients with cardiovascular disease and periodontal disease (17 patients), P+NAFLD group - patients with liver disease (NAFLD) and periodontal disease (19 patients) and P+SYS group - patients with at least two of the systemic diseases (DM, CVD, NAFLD) in the presence of periodontal disease (46 patients).

For the study, we analyzed the data recorded after medical and dental history, examination of clinical aspects, periodontal assessment, radiographic and serological analyzes. We recorded information regarding demographic data (patient's age, environment, gender), working and living conditions, vicious habits, medical history, dental history, patient's hygiene, history of periodontal disease (duration of the disease, onset and evolution over time). The O'Leary Index for bacterial plaque control record has been used for oral hygiene status. The main reason for the last visit to dental services was gingival bleeding when brushing, spontaneous bleeding, calculus, swollen or red gingiva, halitosis, masticatory deficiency, esthetic and functional deficiencies in the missing tooth regions, dental caries, endodontic problems, prevention and treatment. The following data were related to periodontal disease, so the number of missing teeth was recorded, the number of teeth with periodontal pockets measured at different depths (between 4-5 mm, 6-7 mm, over 7 mm), the degree of bleeding, the level of attachment loss and the periodontal diagnosis of the patient.

Serological analyzes of each patient were consulted: blood sugar level, total cholesterol, hepatic enzymes - transaminases ALT and AST, triglycerides and cholesterol.

The data were analyzed and statistically processed using the *Microsoft Excel Data Analysis Tools Pack extension*.

RESULTS

The mean age of the patients included in the study was 47.33 years. The average age of the subjects groups was 43.33 in P group, 54.21 in P+DM group, 46.56 in P+CVD group, 44.88 in P+NAFLD group and higher, 59.55 in P+SYS group.

Human environments are complex and different, influencing the success rate of treatments depending on the availability and information accumulated. Of the 181 patients, 135subjects (74.58%) were from urban areas and the rest, 46 subjects (25.42%) from rural areas.

The main reason for the last visit to dental services is represented in the first table.

The data regarding the age of periodontal diagnosis for each subject group is presented in the first figure.

On average the O'Leary index for P group was 38.92%, for P+DM 29.45%, for P+CVD 22.42%, for P+NAFLD 33.21% and for P+SYS was 38.65%. Most patients had a poorly controlled bacterial biofilm with negative consequences on periodontal disease.

Patients with periodontal disease and diabetes or cardiovascular disease had 4-9 teeth lost. As well as patients with periodontal disease associated with cardiovascular disease and NAFLD, over 56% of them did not have 4-9 teeth on the dental arches (tab. II).

TABLE I

Specific issues that are presented at the medical visit

The main reason	Number	Percent	P	P+DM	P+CVD	P+NAFLD	P+SYS
Bleeding	45	24,86%	35,55%	26,66%	17,77%	6,66%	
Calculus	31	17,13%	29,03%	12,90%	25,80%	25,80%	6,
Red gingiva	27	14,91%	22,22%	25,93%	18,52%	14,81%	18
Halitosis	24	13,26%	12,50%	33,33%	16,66%	16,66%	20
Masticatory deficiency	15	8,29%	13,33%	33,33%	13,33%	13,33%	26
Esthetic and functional deficiency	20	11,05%	30,00%	30,00%	15,00%	10,00%	15
Dental caries	8	4,42%	12,50%	25,00%	25,00%	12,50%	25
Endodontic problems	6	3,31%	16,66%	16,66%	0%	33,33%	33
Prevention and treatment	5	2,77%	40,00%	20,00%	0%	20,00%	20

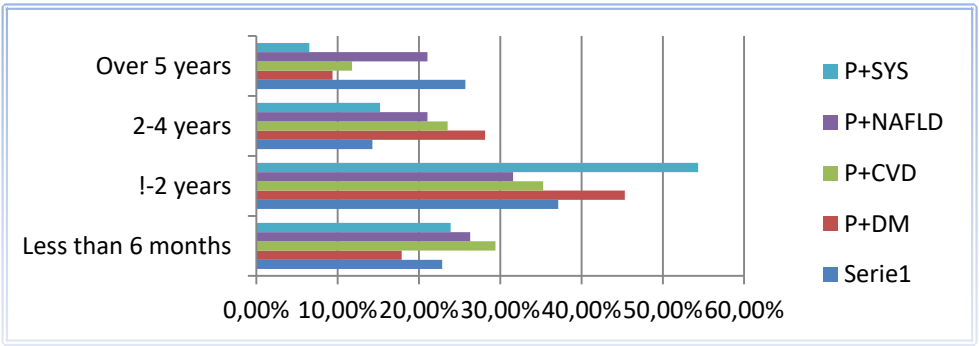

Fig. 1. The age of diagnosis for periodontal disease.

TABLE II

Average tooth loss for each group

Patients groups	0-3 lost teeth	4-9 lost teeth	>10 lost teeth
Group P	51.42%	22.85%	25.73%
Group P+DM	32.82%	37.50%	29.68%
Group P+CVD	23.54%	41.17%	35.29%
Group P+NAFLD	36.86%	31.57%	31.57%
Group P+ SYS	23.91%	56.53%	19.56%

The average number of periodontal pockets with a depth of 4-5 mm is approximately equal for all groups, being 2.43 for the P group, 2.48 for the P+DM, 2.44 for the P+CVD, 2.40 for the P+NAFLD and 2.55 for the P+SYS group. In the case of 6-7 mm periodontal pockets, the P group has an average of 3.11, the P+DM of 3.83, the P+CVD of 3.77, the P+NAFLD of 3.12 and the P+SYS group of 3.95.The average number of periodontal pockets with a depth of more than 7 mm is significantly higher for the P+DM group, being 3.13, compared to the other groups where there were variations of 1.67. The average level of attachment loss is 1.42 mm for the P group, 3.25 mm for the P+SYS, being higher than that of the P+CVD where we found 1.92 mm, for the P+NAFLD which was of 1.76 mm and compared to the P+DM which was

2.21 mm.

The average value of the bleeding index is 11% for the P group, being higher in the P+SYS (19%) compared to the P+DM, P+CVD and P+NAFLD groups, which is 16% (tab. III).

TABLE III

Average values of periodontal measurements

Patients group	The average depth of the periodontal pockets			The average level of attachment loss	The average value of the bleeding index
	4-5 mm	6-7 mm	>7 mm		
P	2.43	3.11	1.08	1.42 mm	11%
P+DM	2.48	3.83	3.13	2.21 mm	16%
P+CVD	2.44	3.77	0.98	1.92 mm	16%
P+NAFLD	2.40	3.12	1.78	1.76 mm	16%
P+SYS	2.55	3.95	2.84	3.25 mm	19%

Regarding the diagnosis of diabetes, most subjects, 169 patients (93.37%) were diagnosed with type 2 diabetes. We recorded in the table the blood glucose value and the glycosylated hemoglobin value, both for patients considered healthy but also for those who confirmed that they suffer from diabetic impairment, for a closer monitoring of the data.HbA1c levels obtained from the medical records for the previous 6 months were ≥ 6.5% (≥ 48 mmol/L).The average levels of glycosylated hemoglobin are 7.2 for subjects included in P+DM group. Blood glucose values in the studied group were between 99.3 mg / dL and 145.5 mg/dL with an average value of 123.5 mg/dL.

The diagnosis of cardiovascular disease in patients in the P+CVD group is hypertension, being found in 12 patients. History of stroke is present in 3 patients. Two of the patients have ischemic cardiomyopathy. The average age of diagnosis of cardiovascular disease is 3 years. The most common type of treatment for patients in the P+CVD group is diuretics in 9 cases, followed by β-blockers in 5 cases and anticoagulants in 3 cases.

Biochemically, patients diagnosed with NAFLD had increased levels of aspartate transaminase (AST) and alanine aminotransferase (ALT). When AST has values higher than ALT, it may indicate the presence of nonalcoholic steatohepatitis or hepatitis C. Patients included in our study had average AST level48.93U/L and ALT level38.21U/L.

Analysis of the mean value of triglycerides in the blood shows an increase in the group of patients diagnosed with NAFLD and higher values for those who also have CVD disease (triglycerides ≥1.70 mmol/L). Triglycerides reference values are normal = < 150 mg/dL (<1.7 mmol/L), mild hypertriglyceridemia = 150-199 mg/dL (1.7-2.3 mmol/L) moderate hypertriglyceridemia = 200-999 mg/dL (2.3-11.2 mmol/L), severe hypertriglyceridemia = 1,000-1,999 mg /dL (11.2-22.4 mmol/L), very severe hypertriglyceridemia = 2,000 mg/dL (22.4 mmol /L). Serum triglyceride levels for patients in the other study groups were normal. Total cholesterol levels lower than 200 mg/dL being the accepted limit for an optimal level, while values above 240 mg/dL are considered high. HDL together with

LDL and triglycerides represent total cholesterol whose values above the normal limit represent an imbalance (tab. IV).

TABLE IV
Triglyceride and cholesterol mean levels

Study group	Triglyceride (mg/dL)	Cholesterol (mg/dL)
Group P	—	—
Group P+DM	152	210
Group P+CVD	155	213
Group P+NAFLD	198	289
Group P+SYS	202	340

DISCUSSION

A two-way relationship, through the spread of oral microorganisms and pro-inflammatory mediators, can be highlighted between periodontal disease and the systemic disorders, such as cardiovascular disease, metabolic syndromes, including DM and NAFLD, cancer and respiratory diseases that could spread oral microorganisms and pro-inflammatory mediators (20, 21).

Fentoğlu *et al.* showed that the mean values of the clinical parameters: plaque index, depth of periodontal pockets, bleeding at probing and the level of clinical attachment were significantly higher in the hyperlipidemia group than in the control group (22).

The preponderance of the data seems to support the concept that periodontitis may contribute to systemic levels of inflammatory mediators and markers associated with an increased risk of cardiovascular disease. Among the most common cardiovascular diseases are ischemic heart disease, stroke, hypertension the main cause in over 95% of deaths (16).

Similar results were presented by Kumar and colleagues in a study aimed at determining the frequency and nature of oral manifestations in hypertensive patients, of whom 85.38% had probing gingival bleeding and marginal gingival erythema and 16.9% patients showed an increase in gingival volume characterized by nodular growth, observed on both the oral and vestibular surfaces of the gingival margin. Inflammatory changes in the gingival mucosa were mainly due to antihypertensive drugs. The frequency of potential oral manifestations in patients with hypertension was significantly high, thus showing an association of gingival and periodontal pathology in hypertensive patients (23).

The average level of attachment loss of 3.25 mm in the group of patients with liver and heart disease and 2.21 in P+DM group, significantly higher compared to patients diagnosed with periodontal disease without other systemic conditions. In the Pham and Tran study published in 2018, the mean value of the level of attachment loss was calculated to be 2.80 mm in their study group represented by diabetic patients (24).

Dhir *et al.* showed that the average value calculated for glycosylated hemoglobin was 7.4% (25).Our study reveals the value of 7.2 for glycosylated hemoglobin in the P+DM group. The blood glucose value during a fasting period, but also after the patients ate was published by Rajhans in 2011. For the group of patients with diabetes there is an average value of 122 mg/dL before meals and 212.36 mg/dL after eating and for the control group 76.24 mg/dL before and after 117.16 mg/dL (26). In our study average value indicates 123.5 mg/dL.

In a study conducted at the clinics of the University of Taubaté the results obtained are similar to those of the current study and showed that the average levels of choles-

terol (192.1 mg / dL ± 40.9) and triglycerides (153.5 mg / dL ± 105.6) in individuals with periodontitis were higher, not statistically different from those without periodontitis (186.1 mg / dL ± 35.4 and 117.5 mg / dL ± 68, respectively) (27).

High values for AST and ALT we concluded in patients with liver disease, in association or not with cardiovascular disease, all other patients presenting normal values on biological tests.

According to studies, high values of AST and ALT are present in patients with periodontal destruction, periodontal pockets and gingival bleeding, being experimentally proved that these biomarkers had high value in serum and saliva in the presence of other different conditions (28-30). According to a study published by Yoneda in 2012, periodontal pathogens were identified more frequently in patients diagnosed with NAFLD than in those in the control group and the initial periodontal treatment decreased AST and ALT levels, this being the reason why we did not include in our study patients previously periodontally treated (31).

CONCLUSIONS

The data suggest that periodontal disease can influence the systemic level of inflammatory mediators in patients with systemic disorders (DM, CVD, NAFLD) through mechanisms that depend on the exposure and control of oral microbial flora. NAFLD is frequently associated with cardiovascular disease or diabetes, by altering lipid and carbohydrate metabolism and the study of these aspects in patients suffering also from periodontal disease, helps to highlight the relationship between these conditions.

IMPACT OF APOE POLYMORPHISM IN A FAMILIAL HYPERCHOLESTEROLEMIA POPULATION (Abstract): Familial hypercholesterolemia is a genetic disease caused by a mutation in one of the genes implied in the low-density lipoprotein (LDL) catabolism, leading to increased seric values of LDL and a very high cardiovascular risk. ApoE is a ligand for the LDL receptor and the polymorphisms at the level of ApoE will alter the lipid profile. **Material and methods:** A cross-sectional study was conducted in the Cardiovascular Rehabilitation Clinic from Iasi Clinical Rehabilitation Hospital between December 1st, 2020, and December 1st, 2021, including 52 patients with familial hypercholesterolemia in the study group and 17 patients in the control group. **Results:** In our research, the patients with ApoE4/E4 had the highest lipid profile concentrations. Statistical significance was observed between ApoE2/E3 and ApoE3/E3, ApoE3/E4 and Apo E4/E4 and between ApoE3/E3 and ApoE4/E4 regarding the creatinine clearance in the familial hypercholesterolemia group. In the same group, statistical significance correlations were observed between ApoE3/E3 and ApoE3/E4 for triglycerides concentration, between ApoE3/E3 and ApoE4/E4 for the glycosylated hemoglobin. **Conclusions:** For a better understanding of the genetic and environmental factors in patients with familial hypercholesterolemia, larger studies are needed, in order to increase their quality of life. **Keywords:** FAMILIAL HYPERCHOLESTEROLEMIA, APOE, LIPID PROFILE, CARDIO-VASCULAR DISEASE, CREATININE CLEARANCE.

Familial hypercholesterolemia is a genetic disease of the metabolism of lipoproteins, causing high levels of low-density lipoproteins (LDL). The loss of function mutations in LDLR, APOB, or PCSK9 genes can lead to homozygous or heterozygous familial hypercholesterolemia. Relatively recent research identified APOE as part of the gene network involved in familial hypercholesterolemia (1, 2). The elevated serum LDL-C induced by any of these mutations promotes atherosclerosis and cardiovascular disease, putting these individuals at a tenfold increased risk of coronary artery disease compared to those without FH. Clinical scoring systems for

the diagnosis of FH are widely used and approved, and numerous sets of criteria have been created, encompassing clinical, biochemical, and genetic factors. The most commonly used criteria are Simon Broome, MedPed and Dutch Lipid Clinic Network (DLCN), the last one being used predominantly in the European countries (3, 4).

ApoE is a component of chylomicrons, very-low-density lipoproteins (VLDL), intermediate-density lipoproteins (IDL), LDL, high-density lipoproteins (HDL), and lipoprotein a (LPa). ApoE regulates the clearance of these lipoproteins from the plasma and the homeostasis of tissue lipid content as a ligand for cell membrane lipoprotein receptors. ApoE is also involved in the catabolism of VLDL particles, inhibits lipoprotein lipase and the triglyceride-rich lipoprotein lipolysis, but may also increase the hepatic production of VLDL by activating the particle assembly cascade. All these data support the involvement of a dysfunctional apoE in the etiology of dyslipidemia (5).

The APOE gene is located on 19q13.2 and encodes for a precursor that follows peptide cleavage and glycosylation, resulting in mature apoE that is secreted as a 299 amino acid protein with a relative molecular mass of 34,200 kDa. According to current literature, one of the main factors affecting the lipid profile levels are ApoE polymorphisms. ApoE2, ApoE3 and ApoE4 are the protein isoforms that are encoded by the most frequent alleles (ε2, ε3, and ε4). Among the population, six phenotypes can be observed: E2/2, E3/2, E3/3, E4/2, E4/3, and E4/4, each of them with different prevalence. Up to date, it is known that the ε2 allele determines a reduction of the cholesterol absorption and also a decrease of the LDL cholesterol values compared to ε4 allele which correlates with high serum cholesterol levels (6, 7). Moreover, the association between dyslipidemia and chronic kidney disease, to be correlated with apoE isoforms, suggesting the importance of apoE polymorphisms study for an accurate prognosis and management plan (8).

MATERIAL AND METHODS

A cross-sectional study was conducted in the Cardiovascular Rehabilitation Clinic from Iasi Clinical Rehabilitation Hospital between December 1st, 2020, and December 1st, 2021. From the 1,499 patients that were admitted in this period, only 52 adults were included in the study. Inclusion selection consisted of patients diagnosed with familial hypercholesterolemia with a DLCN score over 8 that signed the informed consent. Exclusion criteria were considered secondary causes of hypercholesterolemia such as patients diagnosed with severe liver diseases, hypothyroidism, severe chronic kidney disease or nephrotic syndrome, uncontrolled diabetes mellitus or patients that eat meals with high concentrations of saturated and trans-unsaturated fatty acids. The 52 patients were compared to a control group that included 17 adult patients with normal lipid profile who signed the informed consent.

The participants in the study group had a clinical diagnosis of FH, as determined by a DLCN score greater than 8, and were included in the study. A score below 3 points is considered improbable, between 3 and 5 is possible, probable between 6 and 8 points, and more than 8 is considered as a definite clinical diagnosis for familial hypercholesterolemia. One of the criteria used in the diagnosis score is the LDL value, which was adjusted for the patients who

underwent in the last 6 months treatment with statins or ezetimibe. This correction factor was described by Haralambos *et al.* based on a review of 71 original papers gathered prior to the establishment of FH criteria.

A single investigator conducted the anamnesis and physical examination, recording the patients' medical history, body mass index, blood pressure, and heart rate as well as the drug history (including the lipid-lowering therapy and antiaggregant drugs). Regarding the laboratory tests, we included the lipid profile (total cholesterol, LDL, HDL, triglycerides), uric acid, urea, creatinine, blood glucose, and glycated hemoglobin.

DNA was prepared from peripheral blood cells using PureLink® Genomic DNA Kit (Thermo Fisher Scientific). We evaluated relevant mutations in PAI-1 (4G/5G), MTHFR (C677T, A1298C), ACE I/D, apolipoprotein B (R3500Q), and apolipoprotein E (Apo E) E2/E3/E4 by reverse-hybridization using CVD StripAssay kit (ViennaLab Diagnostics, Vienna, Austria).

After PCR amplification with biotinylated primers, PCR products were hybridized directly on the StripAssay® test strips, which contain allele-specific oligonucleotide probes immobilized as parallel lines. The presence of a wild type or/and mutant alleles was visualized by an enzymatic color reaction visible on the strip.

Positively stained lines were analyzed using the online tool StripAssay® Online Calculator (ViennaLab Diagnostics) and for each targeted gene were identified underlying genotypes.

The informed consent was collected from all the patients included in the study and the ethics committee approval was obtained from both "Grigore T. Popa" University of Medicine and Pharmacy Iasi (certificate of approval dated 15th June 2020) and Iasi Clinical Rehabilitation Hospital (certificate of approval dated 25th November 2020).

The data analysis was realized using SPSS 20.0 (Statistical Package for the Social Sciences, Chicago, Illinois). For continuous variables, the data were presented as median with interquartile range or as mean±standard deviation (SD). For categorical variables, the data were presented as the number of cases with percent frequency. Continuous normally distributed variables were compared by Independent Samples t-Test in case of two samples, or by One-Way *ANOVA*, in case of comparisons of more than two samples. Categorical comparisons were performed by Fisher's exact test or by Chi-square test. In the cases where the distribution of the continuous variables didn't satisfy the assumption of normality, we applied the *Mann-Whitney U* test. Spearman correlation coefficient was calculated when evaluating the correlations between continuous variables. A statistical significance was considered at a two-sided p-value < 0.05.

RESULTS

In this research were enrolled 52 patients that were clinically diagnosed with familial hypercholesterolemia and 17 healthy controls. More than half of the included patients were females (63.5%), with a mean age of 55.5±12.8. Regarding the males, they had a lower mean age of detection 38.88±11.72. Regarding education, most of the patients finished university studies (38.5% from the FH group and 70.5% from the control group) followed by patients that have a bachelor's degree (34.6% *vs.* 11.8%). The patients included

were predominantly married (78.8% from the FH group and 58.8% from the control group). When compared to the control group, the patients diagnosed with FH had more associated pathologies such as atherosclerosis, heart failure, metabolic syndrome, or chronic kidney disease. The first table summarize the general characteristics of the patients included in the study.

Apo E3/E3 was the most frequent genotype observed in our study in both groups (80.8% in the FH group and 64.7% in the control group), followed by Apo E3/E4 form (9.6% in the FH group and 0% in the control group). Apo E2/E3 had a lower frequency (5.8% in the FH group and 23.5% in the control group) and Apo E4/E4 had the lowest frequency (3.8% in the FH group and 11.8% in the control group).

TABLE I.

General characteristics of the patients included in the study

Patients characteristics	**FH**	**Controls**	**p value**
Gender, n (%) Females	33 (63.5)	11 (64.7)	0.927
Gender, n (%) Males	19 (36.5)	6 (35.3)	
Age, years (mean±SD)	55.5±12.80	38.88±11.72	0.000
BMI , kg/m^2 (mean±SD)	28.71±5.22	23.99±5.89	0.003
Lipidic profile, mg/dL (mean±SD)			
Total cholesterol	286.93±55.10	207.24±42.15	0.000
HDL cholesterol	58.52±17.51	46.34±11.12	0.009
Non-HDL cholesterol	228.40±57.52	160.90±43.39	0.000
LDL cholesterol	202.41±45.86	129.62±40.05	0.000
Corrected LDL cholesterol	312.73±91.67	129.62±40.05	0.000
Triglycerides	185.88±120.05	178.07±276.96	0.871
Uric acid, mg/dL (mean±SD)	4.44±1.57	4.45±1.37	0.971
Urea, mg/dL (mean±SD)	36.12±14.50	32.51±7.17	0.328
ATS, n (%)	25 (48.1)	3 (17.6)	0.045
HF, n (%)	10 (19.2)	2 (11.8)	0.024
CKD, n (%)			
Stage 1	12 (23.1)	8 (47.1)	0.009
Stage 2	25 (48.1)	9 (52.9)	
Stage 3A	13 (25.0)	0 (0)	
Stage 3B	2 (3.8)	0 (0)	

ATS – atherosclerosis; BMI – body mass index; CKD – chronic kidney disease; FH – familial hypercholesterolemia; HDL – high density lipoprotein; HF – heart failure; LDL – low density lipoprotein.

Regarding the ApoE genotype (tab. II), statistical significance correlations were observed between Apo E3/E3 and Apo E3/E4 for triglycerides concentration, between Apo E3/E3 and Apo E4/E4 for the glycosylated hemoglobin, urea and creatinine clearance value and between Apo E3/E4 and Apo E2/E3 for the creatinine clearance and also when comparing with the gender. In addition, a p value < 0.05 was observed for the creatinine concentration and for the clearance of creatinine between Apo E3/E3 and Apo E2/E3 and only for the creatinine clearance between Apo E2/E3 and Apo E4/E4.

ATS – atherosclerosis; BMI – body mass index; C- LDL – corrected LDL; HDL – high density lipoprotein; IFG – impaired fasting glucose; LDL – low density lipoprotein; MS – metabolic syndrome; TC – total cholesterol; TG – triglycerides; P1 – statistical significance between ApoE3/E3 and Apo E4/E4; P2 – statistical significance between ApoE3/E3 and ApoE2/E3; P3 – statistical significance between ApoE3/E4 and ApoE2/E3; P4 – statistical significance between ApoE3/E3 and ApoE4/E4; P5 – statistical significance between ApoE2/E3 and ApoE4/E4.

Regarding the patients with FH and Apo E3/E3 genotype, most patients (45.2%) were diagnosed with third-degree hypertension, 11.9% (5 patients) had second-degree hypertension, and only 4 patients (9.5%) presented first-degree hypertension. From the ones who presented Apo E3/E4 genotype, 3 (60%) had first degree hypertension and 1 (20%) had second degree hypertension. When referring to the patients with Apo E2/E3, there was one patient (33%) with second and third-degree of hypertension. A significant correlation between the hypertension and the ApoE genotype has been observed ($p = 0.014$).

In table III it can be observed the statistically significant correlation between Apo E3/E3 and Apo E4/E4 for the BMI value in the patients from the control group.

TABLE III.

Correlations between ApoE genotypes variants in the control group

	Apo E3/E3	Apo E2/E3	Apo E4/E4	P_1	P_2	P_3

ATS – atherosclerosis; BMI – body mass index; C- LDL – corrected LDL; HDL – high density lipoprotein; IFG – impaired fasting glucose; LDL – low density lipoprotein; MS – metabolic syndrome; TC – total cholesterol; TG – triglycerides; P1 – statistical significance between ApoE3/E3 and ApoE2/E3; P2 - statistical significance between ApoE3/E3 and ApoE4/E4; P3 - statistical significance between ApoE2/E3 and ApoE4/E4.

In table IV are compared the lipid profile, and the Apo E genotypes in the FH group. We can observe that the lowest values of the total cholesterol, LDL, corrected LDL, triglycerides and non-HDL are in the patients with Apo E3/E4. Slightly increased values compared to this form can be seen in Apo E2/E3, followed by Apo E3/E3. The highest values of the lipid profile can be observed in the Apo E4/E4 form.

TABLE IV

Lipid profile and Apo E genotypes in the FH group

	Apo E3/E3	Apo E3/E4	Apo E2/E3	Apo E4/E4
Total cholesterol (mean±SD)	289.91±53.66	251.80±76.84	284.33±45.44	316.00±28.28
LDL (mean±SD)	203.45±45.50	175.70±58.63	209.53±29.07	236.70±29.13
Corrected LDL (mean±SD)	318.25±93.79	252.06±56.73	308.03±78.43	355.55±138.95
Triglycerides (mean±SD)	198.74±125.58	112.72±40.02	174.16±128.30	116.35±72.61
HDL (mean±SD)	58.50±17.83	64.22±19.66	46.30±9.36	63.10±15.13
Non-HDL (mean±SD)	231.40±57.81	187.58±62.98	238.03±52.35	252.90±13.15

DISCUSSION

Almigbal *et al.* recently published a study in which they evaluated the role of apolipoprotein E in patients with familial hypercholesterolemia. Regarding the frequency of the studied genotypes, our results are consistent with their study, the most frequent being Apo E3/3 and Apo E3/E4 (9).

Regarding the lipid profile and the Apo E genotypes, Liu *et al.* published in 2021 an article that described the fact that Apo E2/E3 had lower values of total cholesterol and LDL cholesterol compared to Apo E3/E3 and Apo E4/E4, results obtained also by us. The authors describe also that Apo E2/E3 has lower lipid profiles when compared to Apo E3/E4, these results being in contradiction to ours (10). Rodrigues *et al.* studied the relationship between Apo E genotypes and dyslipidemia in six main regions of Portugal. The study included 778 men and 1153 women between the ages of 15 and 74. The authors have shown that there is a relationship between E4 allele and high cholesterol blood levels (11).

In our study, we have observed a statistical significance between E3/E3 and E4/E4 for glycated hemoglobin in the patients diagnosed with familial hypercholesterolemia. Ukola *et al.* performed a study on 271 Caucasian patients diagnosed with diabetes to examine whether there was a link between Apo E polymorphisms and the onset of diabetic complications. The authors observed that the E4-bearing genotypes had a higher risk of developing micro and macrovascular complications in patients diagnosed with non-insulin-dependent diabetes mellitus, regardless the gender, when compared to the carriers of E2 genotype (12).

Our research described a statistical significance regarding the creatinine clearance between Apo E2/E3 and Apo E3/E3, Apo E3/E4 and between Apo E4/E4. Studies suggest that patients with Apo E2 genotype have a low glomerular filtration rate when compared to Apo E3 or Apo E4 carriers, also associating a high concentration in the serum creatinine (13). A recently published review illustrates the existence of Apo E2 homozygote glomerulopathy associated

with the mutations of the apolipoprotein E. A possible explanation for this can be the internalization of the lipoproteins by the macrophages into the cytoplasm, being therefore responsible for the accumulation in the glomerulus of lipoproteins (14). Thus, our results are in accordance with the ones already published.

When referring to the control group, a statistical significance regarding the BMI can be observed between Apo E3/E3 and Apo E4/E4. Tabatabaei-Malazy *et al.* described that the Apo E4 allele had a significant impact on the central obesity (15). According to the Atherosclerosis Risk in Communities (ARIC) study, the most common Apo E genotype that was related to BMI was the Apo E4 form (16). Another study found also that the E4-bearing genotypes (Apo E3/E4 and Apo E4/E4) were correlated with higher waist circumference and obesity in elderly women with a family history of diabetes (17).

CONCLUSIONS

Common ApoE variants are well known to be associated with different concentrations of the parameters included in the lipid profile. In our study, the patients with ApoE4/E4 had the highest lipid profile concentrations. In addition, we observed a low creatinine clearance in patients with Apo E2 genotype when compared to Apo E3 and Apo E4.

Despite the fact that these data are statistically significant, larger studies are needed in order to have a better understanding of the impact of the genetic factors in patients with familial hypercholesterolemia. These findings could improve the quality of life of these patients, with a decrease in morbidity and mortality.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest, and they received no specific funding regarding the scientific research.

NEWS

PROENKEPHALIN CORRELATES WITH THE SEVERITY OF SEPSIS-ASSOCIATED ACUTE KIDNEY INJURY

In this study, 215 patients were enrolled. They were diagnosed as having sepsis (N=109, 50.7%) or septic shock (N=106, 49.3%) according to the Sepsis-3 criteria. The PENK levels were significantly higher in the septic shock group than in the sepsis group (118.7 pmol/L *vs.* 75.7 pmol/L, p=0.02). The PENK levels were also significantly higher in patients with vasopressor use than in those without vasopressor use (116.9 pmol/L *vs.* 72.7 pmol/L, p=0.007) and in the non-survivors than in the survivors (171.5 pmol/L *vs.* 79.8 pmol/L, p<0.001). PENK levels gradually increased according to the increased SOFA renal sub scores and CKD-EPI eGFR categories; this significance was constantly observed across each group (P<0.05, post-hoc test), except for eGFR categories G3a and G3b. Another noticeable finding in this study was the significant association between the PENK quartile and 30-day mortality rate. The present data also support the use of a clinical cut-off for PENK (80 pmol/L). In the groups with poor clinical status or outcomes, including septic shock, vasopressor use, and non-survivors, the median value of PENK levels was higher than the clinical cut-off. PENK could thus be an objective and reliable marker that has the potential to substitute for or augment the current role of the SOFA scoring system in critically ill septic patients. DIETARY PATTERNS IN YOUNG AND MIDDLE-AGED SUBJECTS WITH FAMILIAL HYPERCHOLESTEROLEMIA FROM NORTH-EASTERN ROMANIA (Abstract): Familial hypercholesterolemia (FH) is a genetic autosomal dominant disease that is characterized by very high values of low-density lipoproteins. An unbalanced diet associated with FH will increase the cardiovascular risk of fatal and non-fatal events. **Material and methods:** 32 patients with FH were admitted in the Cardiovascular Rehabilitation Clinic from Iasi Clinical Rehabilitation Hospital between 1st December 2020, and 31st March 2022. Dutch Lipid Clinic Network score was the instrument used for the patient's diagnosis. Nutritional assessment was evaluated through a validated food frequency questionnaire. **Results:** In our study, we have observed that men diagnosed with FH eat more chicken meat, fried food, and fast food, while women have a more balanced diet, which includes vegetables and fruits. Regarding the blood tests, we noticed higher values of triglycerides and uric acid in males when compared to women. Moreover, the HDL cholesterol level was higher in women. Regardless of gender, the subjects with FH lack in eating dairy products. **Conclusions:** As far as we know, this is the first study that evaluates the gender-related eating habits of young and middle-aged patients with FH. The information obtained can form the framework for the implementation of active and comprehensive prevention measures in order to increase the awareness of the disease. **Keywords:** FAMILIAL HYPER-CHOLESTEROLEMIA, FOOD FREQUENCY QUESTIONNAIRE, LIPID PROFILE, DIET, CARDIOVASCULAR RISK.

Familial hypercholesterolemia (FH) is a genetic autosomal dominant disease that is characterized by very high values of low-density lipoproteins (LDL) (1). Due to its genetic component, the LDL values are high since childhood, thus increasing the deposits of cholesterol in the vessels intima and intensifying the atherosclerosis process (2). Recent research declares that without effective treatment, the cumulative risk of a coronary event by the age of 60 is more than 50 percent in men and over 30 percent

in women (3). Moreover, researchers affirm that FH is underdiagnosed and undertreated, thus the necessity to prevent the associated cardiovascular disease and make important lifestyle changes are mandatory for them (4).

In order to make a correct diagnosis, there are three clinical criteria that are used worldwide: Simon Broom criteria (used predominantly in the United Kingdom), MedPed (applied in the United States), and Dutch Lipid Clinic Network criteria (DLCN, applied worldwide and most frequently used). These criteria can put the clinical diagnosis of definite FH, but genetic tests for mutations in the LDL receptor gene, APOB gene, or PCSK9 gene are definite for this diagnosis (5).

The current trend is for an accelerated lifestyle, with late work hours, unbalanced meals, and a sedentary lifestyle. As far as we know, this is the first study that aims to evaluate the gender-related eating habits of young and middle-aged patients with FH. The information obtained can form the framework for the implementation of active and comprehensive prevention measures in order to reduce the risk of fatal and non-fatal future cardiovascular events.
